The etiology of L.J.'s nephrotic syndrome should be identified for specific treatment. Although L.J.'s serum sodium concentration of 132 mEq/L is low, it reflects dilution secondary to fluid excess. Salt restriction is therefore important to control L.J.'s generalized edema.[23] For most nephrotic patients, modest dietary sodium restriction to approximately 50 mEq/day may be sufficient to maintain neutral sodium balance.[22,23] For nephrotic patients who are very sodium avid (urine sodium concentration < 10 mEq/L), sufficient restriction is difficult to achieve. Thus, slowing the rate of edema formation rather than hastening its resolution should be the goal of therapy for these patients.[23] Bed rest reduces orthostatic stimulation of the renin–angiotensin–aldosterone and sympathetic systems, thereby favoring the movement of interstitial fluid into the vascular space.[23] The central blood volume is thus increased and natriuresis and diuresis are facilitated. Prolonged bed rest might, however, predispose these hypercoagulable patients to thromboembolism.[16] Similarly, use of support stockings may reduce the stimulation for sodium retention by redistributing blood volume to the central circulation.[23,29]

DIURETICS

Usually, loop diuretics are the mainstay of therapy in the management of nephrotic edema.[2,23] In most of these patients, the edema can be removed safely with rapid diuresis without compromising the systemic circulation, probably because of the rapid refilling of the plasma volume by interstitial fluid.[23] Nevertheless, as the edema resolves, the rate of fluid removal and weight loss should be decreased to avoid compromising the effective circulating volume. The patient should be monitored for the development of orthostatic hypotension.

Infusions of albumin can expand the plasma volume; however, it is expensive, the relief is temporary, and it should therefore be used only for resistant edema.[30] In patients who are resistant to the aforementioned measures, extracorporeal fluid removal, namely ultrafiltration, may be necessary.[23,31]

L.J. was initially treated with IV furosemide 60 mg twice daily and placed on a low-sodium (50 mEq), low-fat, high-complex carbohydrate diet that consisted of 0.8 g/kg protein of high biologic value with additional protein to match gram-per-gram of urinary protein loss. Fluid was restricted to 1,000 mL/day.[32] He had 5 L of diuresis in 2 days, with resolution of respiratory symptoms and a reduction in the anasarca. Parenteral furosemide was discontinued on the fifth day of hospitalization and oral furosemide 120 mg twice daily was started. After a total weight loss of 12 kg, he was then discharged with instructions to maintain the diet and oral furosemide.

DISORDERS IN OSMOREGULATION

Hyponatremia

Serum sodium concentration reflects the ratio of total body sodium to total body water and is not an accurate indicator of total body sodium. Both hyponatremia and hypernatremia can occur in the presence of a low, normal, or high total body sodium.[33,34]

Because the kidney can excrete greater than 12 to 16 L of free water daily, hyponatremia does not occur unless the water intake overwhelms the kidney's ability to excrete free water (e.g., psychogenic polydipsia),[35,36] or free-water excretion is impaired.[2,37]

Free-water formation requires a normal glomerular filtration rate (GFR), the reabsorption of sodium chloride without water in the thick ascending limb of Henle's loop and the distal convoluting tubule, and the excretion of a dilute urine in the absence of ADH[37] (Fig. 27-1). Therefore, hyponatremia can occur when the kidney's diluting ability is exceeded or impaired owing to volume depletion and nonosmotic stimulation of ADH release or inappropriate stimulation of ADH production.[2,37]

Although plasma sodium is the primary determinant of plasma tonicity, hyponatremia does not always represent hypotonicity.[2,37] In patients with severe hyperlipidemia or hyperproteinemia (e.g., multiple myeloma), pseudohyponatremia can occur because the increased amounts of lipids and proteins displace plasma water, in which sodium ions dissolve, resulting in a lower concentration of sodium per unit volume of plasma.[34,37,38] Normally, water accounts for 93% of the plasma volume, and lipids and proteins make up the rest.[37] The increase in plasma lipid and protein contents expands plasma volume, displaces water, and increases the percentage of solids in plasma.[34,37] Because sodium is distributed only in the aqueous phase, the sodium content per liter of the newly recomposed plasma is thus decreased and the plasma sodium concentration is reduced.[34,37,38] The sodium concentration in plasma water remains the same, however. Because osmolality depends on the solute concentration in plasma water, serum osmolality remains unchanged.[34] Indeed, the measured osmolality is normal. Another example of isotonic hyponatremia can be found when a large volume of isotonic mannitol irrigant is used during prostate surgery.[34,37] Absorption of the irrigation solution can result in severe hyponatremia but normal osmolality. In contrast, use of large amounts of isotonic sorbitol and isotonic, or slightly hypotonic, glycine solutions during urologic surgery can cause the hypotonicity as a late complication.[34,37] Similar to mannitol, sorbitol and isotonic glycine initially distribute only in the extracellular space, resulting in hyponatremia without a change in osmolality.[37] Unlike mannitol, both sorbitol and glycine are later metabolized, leaving water behind to result in hypotonicity. The severe hypotonic hyponatremia, in conjunction with the neurotoxic effects of glycine and its metabolites, puts the patient at significant risk for severe neurologic symptoms (Table 27-1).[37,39]

CASE 27-4

QUESTION 1: T.T., a 63-year-old man with end-stage renal disease caused by diabetic nephropathy, is receiving chronic ambulatory peritoneal dialysis. Because of dietary and fluid noncompliance, T.T. complained of shortness of breath (SOB) and his dialysis prescription was adjusted to include six cycles of 2.5% peritoneal dialysis solutions. Today, his laboratory values are as follows:

Na, 128 mEq/L
K, 4 mEq/L
Cl, 98 mEq/L
Total CO_2, 24 mM
BUN, 50 mg/dL
Creatinine, 6 mg/dL
Glucose, 600 mg/dL

Evaluate T.T.’s plasma osmolality. What is the etiology of T.T.’s hyponatremia?

Table 27-1

Clinical Presentation and Treatment of Hyponatremia

Na+ and H_2O Status	**Clinical Presentation/Cause**	**Treatment**
Edematous, Fluid Overload (Hypervolemic, Hypotonic)		
↑ Total body Na+–↑↑ Total body H_2O	Cirrhosis/HF/nephrotic syndrome: A ↓ in renal blood flow activates renin–angiotensin system. ↑ Aldosterone leads to ↑ Na+, and ↑ ADH leads to free H_2O retention. Urine Na+ is low (0–20 mEq/L) and urine osmolality ↓. Diuretics can induce paradoxical effects on urine Na+ and osmolality. This form can also occur in patients with renal failure who drink excessive amounts of water. Patients have symptoms of fluid overload (ascites, distended neck veins, edema).	Fluid and Na+ restriction. Correct underlying disorder (e.g., paracentesis for ascites). Diurese cautiously[a]; avoid ↓ ECF and accompanying ↓ tissue perfusion. ↑ BUN may indicate overly rapid diuresis. Conivaptan: Loading dose of 20 mg IV for 30 minutes, followed by 20 mg IV as continuous infusion for 24 hours for an additional 1 to 3 days; may titrate up to maximal dose of 40 mg/day; maximal duration is 4 days after the loading dose. Dedicated IV line recommended and site of peripheral IV lines should be changed every 24 hours. Caution if used together with fluid restriction. Tolvaptan: Start 15 mg PO once daily. Dose may be increased at intervals of at least 24 hours to 30 mg PO once daily and then to a maximum of 60 mg PO once daily as needed. Caution if used together with fluid restriction. Initiate therapy in a hospital setting.
Nonedematous Hypovolemic (Hypotonic with ECF Depletion)		
↓↓ Total body Na+ ↓ Total body H_2O	Occurs in GI fluid loss (e.g., diarrhea) with hypotonic electrolyte-poor fluid replacement, overdiuresis, “third spacing,” Addison disease, renal tubular acidosis, osmotic diuresis. Replacement of fluid losses with solute-free fluid predisposes these patients to hyponatremia. Kidneys	Discontinue diuretics. Replace fluid and electrolyte (especially K+) losses. 0.9% saline preferred unless Na+ deficit[a] severe, then use 3%–5% saline.

	concentrate urine to conserve fluid (urine Na+ <10 mEq/L). Symptoms: nonedematous; ECF depletion (collapsed neck veins, dehydration, orthostasis). Neurologic symptoms: (see Hyponatremia: Neurologic Manifestations in text).	
Nonedematous, Normovolemic (Normovolemic, Hypotonic)		
↓ Total body Na+ ↑ Total body H_2O	SIADH[b]: Hyponatremia, hypo-osmolality, renal Na+ wasting (>40 mEq/L), absence of fluid depletion, $U_{osm} > P_{osm}$, normal renal and adrenal function. Free H_2O retained while Na+ lost. Causes: (a) ADH production (infectious disease, vascular disease, cerebral neoplasm, cancer of lung, pancreas, duodenum); (b) exogenous ADH administration; (c) drugs; (d) psychogenic polydipsia.	See earlier for dosing of VRA (conivaptan and tolvaptan) Chronic treatment: Restrict fluids to less than urine loss. Demeclocycline (300–600 mg BID) induces reversible diabetes insipidus. Emergency treatment for unresponsive patients includes furosemide diuresis to achieve negative H_2O balance with careful replacement of Na+ and K+ using hypertonic saline solutions.[c]

[a] Remove estimated excess free water with IV furosemide (1 mg/kg). Repeat as necessary. Because furosemide generates a urine that resembles 0.5% NaCl, urine losses of sodium and potassium must be carefully measured and replaced hourly with hypertonic salt solutions. Correction rate: 1 to 2 mEq Na/hour in symptomatic patients; 0.5 mEq/hour in asymptomatic patients.

[b] Estimate sodium deficit: (mEq) = TBW (sodium desired − sodium observed). Rate of sodium and fluid repletion used depends on severity. Mild: replace with NS. First one-third for 6 to 12 hours at a rate of <0.5 mEq/L/hour, remaining two-thirds for 24 to 48 hours. Severe (e.g., seizures): Use 3% to 5% saline, rate gauged by patient's ability to tolerate sodium and volume load. Monitor central nervous system function, skin turgor, blood pressure, urine sodium, signs of sodium or water overload, especially in patients with cardiovascular, renal, and pulmonary disease.

[c] Total body water (TBW) = 0.6 L/kg × weight in kg (for men) and 0.5 L/kg × weight in kg (for women). TBW excess = TBW − [TBW (observed serum NA)/(desired serum NA)].

ADH, antidiuretic hormone; BID, twice daily; BUN, blood urea nitrogen; HF, heart failure; ECF, extracellular fluid; GI, gastrointestinal; IV, intravenous; NS, normal saline (0.9% Na); PO, orally; SIADH, syndrome of inappropriate ADH; TBW, total body weight.

T.T.'s effective plasma osmolality is calculated to be 289 mOsm/L, of which 33 mOsm/L is contributed by the hyperglycemia. The slow utilization of glucose, because of the lack of insulin, causes water to move from the intracellular compartment into the plasma space because of the increased tonicity, thereby lowering the plasma sodium concentration.[34,37] Despite the lowered plasma sodium concentration, the plasma osmolality is normal because of hyperglycemia. Hence, no symptoms attributable to hypo-osmolality are observed. Indeed, when serum glucose is normalized with insulin and hydration, the serum sodium level will increase to approximately 136 mEq/L. For each 100-mg/dL increment in serum glucose, serum sodium decreases by 1.3 to 1.6 mEq/L.[34,37] Use of hypertonic mannitol or glycine solutions in patients with cerebral edema also results in a hyperosmolar hyponatremia.[34]

Hypotonic Hyponatremia with Decreased Extracellular Fluid

CASE 27-5

QUESTION 1: Q.B., a 30-year-old male athlete who has had multiple bouts of diarrhea for the last several days, has been drinking a sports drink to keep himself from getting dehydrated. His vital signs include supine BP, 145/80 mm Hg, and pulse, 70 beats/minute; standing BP, 128/68 mm Hg, and pulse, 90 beats/minute. Respiratory rate (RR) is 12 breaths/minute, and he is afebrile. His skin turgor is mildly decreased and laboratory data are the following:

Na, 128 mEq/L
K, 3.0 mEq/L
Cl, 100 mEq/L
Bicarbonate, 17 mEq/L
BUN, 27 mg/dL
Creatinine, 1.2 mg/dL

Urinary sodium and chloride were both less than 10 mEq/L. Assess Q.B.'s electrolyte and fluid status. What is the etiology of Q.B.'s hyponatremia?

Q.B. has true hypotonic hyponatremia with ECF depletion, suggesting that his total body sodium deficit is greater than that of total body water.[34] His poor skin turgor, orthostasis, prerenal azotemia, and low urinary sodium are consistent with volume depletion. The urinary sodium concentration helps distinguish between renal and nonrenal losses that result in the sodium and water deficits.[15,34,40] When the plasma volume is depleted, the urinary sodium concentration is less than 10 mEq/L, suggesting appropriate renal sodium conservation.[15] This is usually seen in patients such as Q.B. with GI fluid loss as in vomiting, diarrhea, or profuse sweating.[34,37,40]

Other causes of hypotonic hyponatremia are less likely in Q.B. They include surreptitious cathartic abuse and "third spacing," or accumulation of ECF in the abdominal cavity during acute pancreatitis, ileus, or pseudomembranous colitis.[37,40] If the urinary sodium is less than 20 mEq/L in the face of volume depletion, renal salt wastage should be considered.[15,37,40] The potential causes of this latter problem include diuretic use,[41–44] adrenal insufficiency,[44] and salt-wasting nephropathy[35] (e.g., chronic interstitial nephritis, medullary cystic disease, polycystic kidney disease, obstructive uropathy, and cisplatin toxicity[44,45]). In patients with renal insufficiency, neither the urinary sodium nor chloride concentration is a reliable index of volume status.[15]

Volume depletion leads to increased reabsorption of sodium and water in the proximal tubule and, thus, decreased sodium delivery to the diluting segments for free-water formation.[34,37,40] Decreased effective arterial volume is also a potent nonosmotic stimulus for ADH release.[9,10] These factors combine to dampen the ability of the kidney to form dilute urine and result in high urine osmolality despite a low serum sodium concentration.[34,37,40] Although the fluid lost in diarrhea is hypotonic, it is the replacement of fluid lost with an even more hypotonic fluid such as the sports drink or tap water that causes hyponatremia in patients such as Q.B.[37,40]

Q.B.'s diarrhea probably caused loss of potassium and bicarbonate through the GI tract, resulting in hypokalemia and hyperchloremic metabolic acidosis. The potassium depletion can sensitize ADH secretion in response to hypovolemic stimuli, and the hypokalemia can also lead to hyponatremia.[37] The cellular efflux of potassium causes cellular uptake of sodium, further reducing the serum sodium concentration.

CASE 27-5, QUESTION 2: How should Q.B.'s hyponatremia be treated?

The treatment of hypovolemic hyponatremia involves sodium replacement to correct the deficit. The sodium deficit can be estimated by the following formula:

$$\begin{aligned}\text{Na Deficit} &= \text{TBW} \times (\text{Desired} - \text{Current Na concentration})\\ &= 0.6\ \text{L/kg} \times 70\ \text{kg} \times (140 - 125\ \text{mEq/L})\\ &= 630\ \text{mEq} \qquad \text{(Eq. 27-8)}\end{aligned}$$

Recall that TBW = 0.6 L/kg × weight in kg for men and 0.5 L/kg × weight in kg for women.

Approximately one-third of the deficit can be replaced over the course of the first 12 hours at a rate of less than 0.5 mEq/L/hour. The remaining amounts can be administered over the course of the next several days.

The use of isotonic sodium chloride solution is ideal for the treatment of hyponatremia associated with volume depletion. As renal perfusion is restored, free water will be excreted with appropriate retention of sodium.[40] Because Q.B. has only mild volume depletion, oral replacement fluids can be given. Oral solutions containing both electrolyte and glucose[46] or rice-based solutions[47] are ideal for the management of persistent fluid loss. Glucose not only provides calories but also promotes the intestinal absorption of ingested sodium.[48] Because the rice-based solution provides more glucose and amino acids, both of which can promote intestinal sodium absorption, it is more effective than glucose alone.[2,48]

In patients with renal salt wasting, the ongoing daily sodium loss should also be taken into consideration when estimating the amount of replacement. Potassium should be given to correct hypokalemia, thereby reducing the hyponatremia as well. The serum sodium concentration may rise faster than expected because as tissue perfusion is restored, sodium delivery to the distal tubules will increase and ADH secretion will be suppressed appropriately.[34,37,40] In the absence of ADH, increased free-water excretion will improve the serum sodium concentration faster than initially estimated.

Hypervolemic Hypotonic Hyponatremia

CASE 27-6

QUESTION 1: T.W., a 55-year-old man with a longstanding history of alcoholic liver cirrhosis, is admitted to the hospital for worsening shortness of breath. His medical history includes portal hypertension, esophageal varices, and noncompliance with dietary restriction and medications. His BP is 120/60 mm Hg; pulse, 100 beats/minute; RR, 20 breaths/minute. He is afebrile. Physical examination reveals a jaundiced man in respiratory distress. His jugular vein is flat and lung examination reveals bilateral basal rales. Abdominal examination shows tense ascites with hepatomegaly and spider angiomas (telangiectasias resembling a spider). He has 1+ pedal edema bilaterally. Laboratory data on admission are as follows:

Na, 127 mEq/L
K, 3.4 mEq/L
Cl, 95 mEq/L
Total CO_2 content, 24 mEq/L
BUN, 10 mg/dL
Serum creatinine (SCr), 1.2 mg/dL
Albumin, 2.5 g/dL
Urine Na, <10 mEq/L
Osmolality, 380 mOsm/L

Identify the possible causes of hyponatremia in T.W. and discuss its pathophysiology. How should he be treated?

T.W. had no history of vomiting or diarrhea and had stopped using diuretics before admission. The physical findings of ascites and bilateral edema are not consistent with volume depletion but indicate a sodium-excess state. Both sodium and water retention occur, but the disproportionate accumulation of ingested water relative to sodium leads to hyponatremia.[34,37,40]

Cirrhotic patients who are susceptible to developing hyponatremia have a decreased effective arterial blood volume.[24,37,46,47] The low urinary sodium concentration suggests that the effective arterial blood volume was decreased.[15] The high urinary osmolality in the face of hypotonic hyponatremia suggests, however, that the release of ADH has been stimulated, impairing free-water excretion. Peripheral vasodilation causes decreases in systemic arterial BP despite a normal-to-high cardiac output. This, along with splanchnic venous pooling and decreased oncotic pressure secondary to hypoalbuminemia, decreases renal perfusion in patients with cirrhosis, such as T.W.[22,28,46] Decreased renal perfusion activates the renin–angiotensin–aldosterone system, the sympathetic nervous system, and the release of ADH. Reabsorption of sodium and water in the proximal tubules is enhanced, diminishing sodium and water delivery to the distal segments of the nephron. The diluting capacity of the kidney is thus impaired. Increased secretion of antidiuretic hormone also promotes free-water reabsorption at the collecting tubule and contributes to the hyperosmolality of urine and hyponatremia. The hypervolemic hyponatremia is also seen in patients with heart failure (HF) and nephrotic syndrome[24–28] and in patients with chronic renal disease who drink excessive amounts of water[37,40] (see Chapter 14, Heart Failure). As the GFR decreases, distal delivery of sodium is reduced and the ability to generate free water is impaired. In addition, the capacity to conserve sodium is impaired in these patients.[15]

Most patients who are edematous and hyponatremic are asymptomatic, but the degree of hyponatremia probably reflects the severity of the underlying disease.[46,47,49] Unless an acute decrease in serum sodium occurs, rapid therapeutic correction is not warranted.[37,40,46,47,50] Water restriction, the mainstay of therapy, is determined by the degree of hyponatremia and the severity of symptoms. Sodium restriction and judicious use of diuretics may help reduce the edematous state, but the patient must be monitored closely to avoid prerenal azotemia, which suggests overaggressive diuresis. Furthermore, diuretics can induce or worsen hyponatremia and volume depletion by impairing the diluting capacity of the kidney.[43–47]

T.W. had abdominal paracentesis to relieve respiratory discomfort with no sequelae. He was then prescribed a 1,000-mg sodium diet, and water was restricted to 500 mL/day. Diuretic therapy was resumed.

Normovolemic Hypotonic Hyponatremia

CASE 27-7

QUESTION 1: C.C., a 50-year-old man who was diagnosed recently with small-cell lung carcinoma, was brought to the ED by his family because he had become progressively lethargic and stuporous during the past week. Laboratory data revealed the following:

Serum Na, 110 mEq/L
K, 3.6 mEq/L
Cl, 78 mEq/L
Bicarbonate, 22 mEq/L
BUN, 10 mg/dL
SCr, 0.9 mg/dL
Glucose, 90 mg/dL
Serum osmolality, 230 mOsm/kg
Urine osmolality, 616 mOsm/kg
Urine Na, 60 mEq/L

Arterial blood gas (ABG) examination at room air showed pH, 7.38; PCO_2, 38 mm Hg; and PO_2, 80 mm Hg. On physical examination, C.C. was normotensive, appeared to be euvolemic, and had no edema detected. Review of his medical records showed normal adrenal and thyroid function. C.C. was currently not using any medications. On admission to the ward, C.C. weighed 60 kg and was given 1 L of normal saline, after which his serum sodium concentration was 108 mEq/L. Identify the cause of hyponatremia in C.C. and describe its pathophysiology.

In a patient with hypo-osmolar hyponatremia with a volume status that is apparently normal, the differential diagnosis[40] includes hypothyroidism,[51] cortisol deficiency,[52] a reset osmostat,[53] psychogenic polydipsia,[36,38] and the syndrome of inappropriate antidiuretic hormone secretion (SIADH),[54–56] which is a diagnosis of exclusion. C.C.'s normal thyroid and adrenal function tests exclude hypothyroidism and cortisol insufficiency as causes of his hyponatremia. The inappropriately elevated urine osmolality (>100 mOsm/kg) is inconsistent with psychogenic polydipsia or a reset osmostat, because free-water excretion is usually not impaired in these disorders. These findings, in addition to a urine sodium concentration greater than 40 mEq/L and a normal acid–base and potassium balance, are consistent with SIADH.[37,55,56]

In SIADH, the ADH secretion is considered inappropriate because of its persistence in the absence of appropriate osmotic and hemodynamic stimuli. Water ingestion is essential to the development of hyponatremia in SIADH because persistent ADH activity impairs water excretion, resulting in expansion of body fluids and hypo-osmolar hyponatremia. Edema rarely is apparent because only one-third of the retained water resides in the extracellular space and the sodium homeostatic mechanisms are intact.[34,40] The ECF expansion activates volume receptors and results in natriuresis. At steady state, urinary sodium excretion reflects sodium intake and is usually greater than 40 mEq/L, as in C.C.'s case. Nonetheless, if sodium intake is reduced severely, the urinary sodium concentration may become less than 40 mEq/L.[37]

The causes of SIADH are diverse and are shown in Table 27-1. Four different patterns of inappropriate ADH release have been identified.[37] No correlation has been found between these patterns and the underlying causes of SIADH, however. Mechanisms for drug-induced SIADH include ADH-like action on the collecting tubule, central stimulation of ADH release, and potentiation of the ADH effect.[37,57] Small-cell lung carcinoma is the most likely cause of C.C.'s SIADH.

CASE 27-7, QUESTION 2: Why was C.C.'s serum sodium concentration lower after the saline infusion?

Isotonic sodium chloride solution (154 mEq/L each of sodium and chloride ions, or 308 mOsm/L) initially will increase the plasma sodium concentration because its osmolality is higher than C.C.'s.[58] C.C., however, has a relatively fixed urine osmolality of 616 mOsm/kg owing to persistent ADH activity; thus, he must excrete an osmolar load of 616 mOsm in a volume of 1,000 mL of urine at steady state. Because a total of 1 L of fluid containing 308 mOsm was administered, all the solutes were excreted in 500 mL of urine output, and 500 mL of free water was retained to cause a further dilution of sodium and a reduction in serum sodium concentration.[37,58]

p. 577

p. 578

Neurologic Manifestations

CASE 27-7, QUESTION 3: Why are C.C.'s neurologic manifestations characteristic of hyponatremia?

As the plasma osmolality declines, the osmotic gradient created across the blood–brain barrier favors the movement of water into the brain and other cells.[37,40] Water movement from the cerebrospinal fluid into the cerebral interstitium results in cerebral edema. Brain swelling is limited by the meninges and cranium, however, giving rise to increased intracranial pressure and neurologic symptoms. The degree of cerebral overhydration and the rapidity of its development appear to correlate with the severity of symptoms.[37,40]

When hyponatremia develops in less than 2 to 3 days or the rate of decline in serum sodium is greater than 0.5 mEq/L/hour, the situation is regarded as acute.[37,59,60] The patient often becomes symptomatic when serum sodium concentration falls to 125 mEq/L; early complaints include nausea, vomiting, and malaise.[37,61] Severe symptoms occur more commonly when the serum sodium falls to less than 120 mEq/L and the rate of decline is greater than 0.5 mEq/L/hour. The patient may present with headache, tremors, incoordination, delirium, lethargy, and obtundation. As the serum sodium drops less than 110 to 115 mEq/L, seizure and coma may result.[37,61] On occasion, severe brain edema leads to transtentorial herniation and eventually death. Women, especially those who are premenopausal, apparently are more susceptible to the development of severe neurologic symptoms and irreversible neurologic damage than are men.[62,63]

In contrast to acute hyponatremia, patients who are chronically hyponatremic are usually asymptomatic.[37,59] If present, symptoms are usually vague and nonspecific and tend to occur at lower serum sodium concentrations than those associated with symptomatic acute hyponatremia.[37,59,61] The patient may experience anorexia, nausea, vomiting, muscle weakness, and cramps. Irritability, hostility, confusion, and personality changes may also be seen. At extremely low sodium levels, stupor and, rarely, seizures have been reported.

Brain Adaptation to Hyponatremia

The difference in symptoms between acute and chronic hyponatremia is related to cerebral adaptation to hypotonicity. Two adaptive mechanisms are important in minimizing cerebral edema.[37,40,64,65] First, cerebral overhydration increases the hydrostatic pressure in the cerebral interstitium, which results in the movement of fluid from the cerebral interstitial space to the cerebrospinal fluid. Second, the extrusion of intracellular solutes reduces cellular osmolality, which in turn enhances water movement out of the cells. Sodium and potassium ions are the initial solutes extruded, followed over a period of hours to days by osmolytes such as inositol, glutamine, glutamate, and taurine.[64] Therefore, when the serum sodium concentration falls faster than the onset of brain osmotic adaptation processes, serious and permanent neurologic damage can occur.[37,40,64,65] On the other hand, when hyponatremia develops over the course of 2 to 3 days, symptoms are not usually seen unless the serum sodium concentration is reduced markedly.

It is often difficult to determine the acuity and chronicity of hyponatremia. Unless an obvious cause for acute hyponatremia is found, assume that the condition is chronic.[37,59,60,65] A rapid decline in serum sodium concentration usually suggests that hypotonic fluid was administered to a patient with a condition that overwhelms or impairs renal water excretion. These conditions include psychogenic polydipsia[35,36]; postoperative hyponatremia[62,63,66,67]; postprostatectomy syndrome[39]; and administration of thiazide diuretics,[41,42] parenteral cyclophosphamide,[68] oxytocin,[69] and arginine vasopressin or its analogs.[57] C.C.'s symptoms appear to have developed over the course of 7 days and are consistent with chronic hyponatremia.

Rate of Correction of Hyponatremia

CASE 27-7, QUESTION 4: How should C.C.'s hyponatremia be managed?

C.C.'s water excess should be calculated to estimate the amount of water that should be removed to achieve the desired sodium concentration.

$$\text{Water excess} = \text{TBW} - \text{TBW}\ (\text{Observed serum Na}/\text{Desired serum Na}) = 36\ \text{L} - 36\ \text{L}\ (110\ \text{mEq/L}/120\ \text{mEq/L}) = 3.0\ \text{L} \qquad \text{(Eq. 27-9)}$$

where

$$\text{TBW} = 0.6\ \text{L/kg} \times 60\ \text{kg} = 36\ \text{L} \qquad \text{(Eq. 27-10)}$$

The treatment of hyponatremia has been controversial. Severe hyponatremia is associated with high rates of morbidity and mortality, but its treatment can also result in morbidity. The rate of correction has been implicated as the main cause of complications.[59–61,65,70–72]

It takes time for the brain to lose osmolytes to reduce cerebral swelling during hyponatremia; conversely, the rate of reaccumulation of these osmolytes must keep pace with the rise in serum sodium concentration to avoid brain dehydration and damage. Indeed, rapid correction of hyponatremia can cause a constellation of neurologic findings known as osmotic demyelination syndrome (ODS).[71,72] Clinical manifestations usually are delayed and occur one to several days after the treatment has been started. Neurologic findings include transient behavioral changes, seizures, akinetic mutism in mild cases, and features of a pontine disorder in severe cases (pseudobulbar palsy, quadriparesis, and coma). In some patients, the damage is irreversible, and central pontine myelinolysis can be documented in fatal cases.

Patients at greatest risk for osmotic demyelination are those with severe hyponatremia lasting greater than 2 days and those in whom the rate of correction of hyponatremia is greater than 12 mEq/L in any 24-hour period.[65,71,72] Hypokalemia, which was found in about 90% of patients with ODS associated with rapid hyponatremia correction, has been suspected as a predisposing factor in the development of ODS.[72] Because the etiology of this complication is unclear, it may be beneficial to correct the hypokalemia before correcting the severe hyponatremia.[72]

Retrospective reviews suggest that acute hyponatremia can be treated safely at a rate of 1 mEq/L/hour initially, until the serum sodium concentration reaches 120 mEq/L. Thereafter, the rate of correction should be reduced to less than or equal to 0.5 mEq/L/hour, such that an increment in sodium concentration does not exceed 12 mEq/L in the first 24 hours.[59,73] Slow correction is indicated for severe chronic hyponatremia. No neurologic complications were seen in patients with severe hyponatremia when the average rate of correction to serum sodium was less than 0.55 mEq/L/hour or when the increase in serum sodium was less than 12 mEq/L in 24 hours or less than 18 mEq/L in 48 hours.[73]

In C.C., the serum sodium concentration should be raised to approximately 120 mEq/L at a correction rate of approximately 0.5 mEq/L/hour, using hypertonic saline and furosemide. Serum sodium concentrations should be monitored closely because the equation for calculating water excess does not take into account insensible loss, which can increase the rate of sodium correction.

The use of normal saline is not useful in C.C. because he excretes salt normally (urine sodium, 60 mEq/L). C.C.'s sodium deficit is as follows:

$$(0.6\ \text{L/kg})(60\ \text{kg})(120 - 110\ \text{mEq/L}) = 360\ \text{mEq} \qquad \text{(Eq. 27-11)}$$

Because 1 L of 3% sodium chloride solution contains 513 mEq of sodium, approximately 700 mL of 3% saline solution, which contains 360 mEq of sodium, will be required to correct the sodium deficit. The recommended serum sodium concentration correction rate is 0.5 mEq/L/hour; therefore, a minimum of 20 hours will be needed to raise the serum sodium concentration by 10 mEq/L (from 110 to 120 mEq/L). The amount of sodium replacement to safely increase the serum sodium concentration can be determined by the product of the rate of replacement (0.5 mEq/L/hour) and TBW (36 L, Eq. 27-10)—that is, 18 mEq/hour. The maximal rate of infusion of 3% saline, which contains 0.513 mEq/mL of sodium, is therefore 35 mL/hour (18 mEq/hour)/(0.513 mEq/mL). A rate of 30 mL/hour, therefore, is appropriate to safely replace C.C.'s sodium deficit.

Because calculations for water excess and sodium deficits are only approximations, the patient's serum osmolality, serum sodium, and clinical response must be monitored closely. Urinary losses can be replaced with 3% sodium chloride solution and appropriate amounts of potassium.

Chronic Management of the Syndrome of Inappropriate Antidiuretic Hormone Secretion

CASE 27-7, QUESTION 5: How should C.C.'s SIADH be managed chronically?

SIADH is usually transient if the underlying cause can be removed. Chronic SIADH can occur, however, as illustrated by C.C. Water restriction sufficient to create a negative water balance is the primary therapy and should be attempted first.[37,40] In general, all fluids, not just water, should be included in the restriction. Salt intake, however, should not be reduced or solute depletion can occur. The extent of fluid restriction depends on urine output, the amount of insensible water loss, and urine osmolality. For a given amount of solute excretion, patients with a high urine osmolality require a smaller volume of urine (i.e., more water retained) than those with a lower urine osmolality (i.e., less water retained). Hence, more stringent water restriction is required in patients with a high urine osmolality. Commonly, several days of restriction are needed before a significant increase in plasma osmolality is observed.

When fluid restriction fails to reverse the hypo-osmolar state or when the patient is unwilling or unable to comply with the severe fluid restriction, drugs that antagonize the effect of ADH can be used.[37,40] These include loop diuretics,[74,75] demeclocycline,[76] and lithium.[77] Furosemide (20–40 mg/day) reduces urine osmolality by blocking the concentrating ability of the kidney.[74] Demeclocycline and lithium directly impair the response to ADH at the collecting tubule, inducing nephrogenic diabetes insipidus.[76,77] Demeclocycline (300–600 mg twice daily) is usually better tolerated than lithium. Its effect on water excretion is delayed for a few days, and it dissipates over a similar period of time after the drug is stopped. Nephrotoxicity has been reported with its use in patients with cirrhosis.[78] Limited data suggest that phenytoin may inhibit ADH secretion, but its effectiveness is questionable.[79] Urea can correct hypo-osmolality by increasing solute-free water excretion and reducing urinary sodium excretion.[80] It has been used effectively, at 30 to 60 g/day, both short term and long term, to reduce the need for fluid restriction.[81] An IV formulation of urea is available commercially; however, for oral administration, 30 g of urea crystals can be dissolved in 10 mL of aluminum–magnesium antacid and 100 mL of water. Orange juice or other strongly flavored liquids can be used to improve palatability.

VASOPRESSIN RECEPTOR ANTAGONISTS

Nonpeptide vasopressin receptor antagonists (VRAs), also known as the "vaptans" or "aquaretic agents," constitute a class of agents used for the treatment of hyponatremia. Arginine vasopressin (AVP), a neuropeptide hormone, plays an important role in maintaining serum osmolality, as well as circulatory and sodium homeostasis.[82,83] AVP exerts its physiologic effects by acting on V1A, V1B, and V2 receptors, causing effects such as vasoconstriction,[84,85] corticotropin release,[86] and water excretion,[87] respectively. V2 receptors are located in the renal collecting tubules and mediate the antidiuretic effects of AVP. Antagonism of the V2 receptors results in aquaresis, which is a unique solute-free and electrolyte-sparing (sodium and potassium) water excretion process in the kidneys. Because circulating levels of AVP are elevated in SIADH, cirrhosis, and HF, VRA can be beneficial in the management of hyponatremia associated with these conditions.

Conivaptan, a mixed V1A and V2 receptor antagonist, was the first VRA approved by the US Food and Drug Administration (FDA) for the treatment of euvolemic and hypervolemic hyponatremia in hospitalized patients.[88] Randomized, double-blind, placebo-controlled trials demonstrated its efficacy in increasing serum sodium concentrations in patients with euvolemic and hypervolemic hyponatremia associated with SIADH and HF, respectively.[88,89] It is administered as an IV infusion and its use is restricted to a short-term (4 days) inpatient use only. Close monitoring of serum sodium concentration is necessary to prevent overly rapid correction of hyponatremia and central pontine myelinolysis that may ensue. Because conivaptan is a potent inhibitor of the cytochrome P-450 3A4 (CYP3A4) enzyme, drug interactions with medications that undergo CYP3A4-mediated metabolism are possible.[82] In addition, patients may experience infusion-site reactions with conivaptan caused by the organic solvent, polypropylene glycol.

Tolvaptan, a selective oral VRA, was approved by the FDA in 2009 for the treatment of hypervolemic and euvolemic hyponatremia in patients with HF, cirrhosis, and SIADH. Because of its selectivity for the V2 receptor, tolvaptan increases urinary excretion of free water (aquaresis) and has less of a blood pressure–lowering effect. As such, it may be more suitable for use in patients with low to normal blood pressure, such as those with HF or cirrhosis. Tolvaptan has been shown to increase serum sodium concentration significantly and correct hyponatremia in patients with SIADH, chronic HF, or cirrhosis.[90] It has also been studied extensively in chronic HF where improvement in signs and symptoms such as reduction of edema and weight, as well as normalization of serum sodium concentrations, were shown.[91,92] However, the use of tolvaptan in HF had no effect on long-term cardiovascular mortality or hospitalization for HF.[93] More recent studies have shown the potential benefits of tolvaptan in patients with autosomal dominant polycystic kidney disease.[94,95] However, hepatic injury was noted in some patients, thus resulting in the release of a safety announcement by FDA to limit tolvaptan's use to no more than 30 days and the removal of the indication for use in patients with cirrhosis.[96] It should not be used also in patients with underlying hepatic disease.

Lixivaptan is another VRAs that is selective for the V2 receptor. Like tolvaptan, they are orally active and thus useful in patients who require chronic therapy or when oral therapy is preferred. Lixivaptan has been studied in patients with hyponatremia from HF, cirrhosis, and SIADH; the results showed significant increases

---

in aquaresis and serum sodium concentrations in both in- and outpatients.[97–101] However, it has yet to receive FDA approval.

Common adverse effects of VRAs include thirst, dry mouth, polyuria, and blood pressure reduction. Aquaretics increase thirst by increasing blood tonicity and urine volume; orthostatic hypotension has been reported.[83,102] These agents are thus contraindicated in hypovolemic hyponatremia. The risk of excessive correction of hyponatremia and the resultant neurologic complications from osmotic demyelination exists with VRA, especially when used in combination with fluid restriction. These agents should therefore be initiated in the inpatient setting at the lowest possible dose and titrated slowly, with close monitoring of serum sodium concentrations and volume status. Additionally, the VRAs are substrates and inhibitors of the CYP3A4 enzyme. As a result, there is a potential for clinically significant drug interactions, particularly with concomitant administration of moderate or strong CYP3A4 inducers or inhibitors.

The VRAs should be used in hyponatremic patients with mild-to-moderate severe neurologic symptoms. Not only have they been shown to maintain normal serum sodium concentrations both short- and long-term but their aquaretic effect could also reduce or eliminate the need for fluid restriction normally required of patients.[90,103] The effectiveness of VRA to correct serum sodium concentration in euvolemic and hypervolemic hyponatremia has been shown. However, their long-term safety with chronic use and their potential benefits on morbidity and mortality still need to be assessed. The high cost of using these agents is also a major barrier to routine clinical use.

Hypernatremia

Hypernatremia can occur under the following conditions: (a) normal total body sodium with pure water loss, (b) low total body sodium with hypotonic fluid loss, and (c) high total body sodium as a result of pure salt gain.[104] Therefore, as in hyponatremia, it is important to assess the volume status of the ECF when evaluating hypernatremia.

Pure water loss can result from the inability of the kidney to conserve water (diabetes insipidus) or from extrarenal water loss through the respiratory tract or the skin.[105] Usually, pure water loss does not cause hypernatremia unless the thirst center is damaged or access to free water is limited.[104]

Hypotonic fluid loss can occur renally as a result of osmotic diuresis, use of loop diuretics, postobstruction diuresis, or intrinsic renal disease. Extrarenally, hypotonic fluid loss can result from diarrhea, vomiting, burns, and excessive sweating.

Pure salt gain can result from the use of hypertonic saline during abortion, sodium bicarbonate administration during cardiopulmonary resuscitation, hypertonic feedings in infants, and, rarely, mineralocorticoid excess.

The management of hypernatremia includes correcting the underlying cause of the hypertonic state, replacing the water deficits, and administering adequate water to match ongoing losses.[104] The pure water deficit can be estimated as follows:

$$\begin{aligned}\text{Water deficit} &= \text{TBW (Observed serum Na/}\\ &\qquad \text{Desired serum Na)} - \text{TBW}\\ &= \text{TBW (Observed serum Na/}\\ &\qquad \text{Desired serum Na} - 1) \qquad \text{(Eq. 27-12)}\end{aligned}$$

where desired serum sodium is usually 140 mEq/L.

The rate at which hypernatremia should be corrected depends on the severity of symptoms and degree of hypertonicity. Too-rapid correction can precipitate cerebral edema, seizures, and irreversible neurologic damage, and can be fatal. For asymptomatic patients, the rate of correction probably should not exceed changes of 0.5 mEq/L/hour in plasma sodium. A rule of thumb is to replace half the calculated deficit with hypotonic solutions over the course of 12 to 24 hours. Any ongoing water loss, including insensible loss, should also be replenished while carefully monitoring the patient’s neurologic status. The remaining deficit can then be replaced during the ensuing 24 to 48 hours. Concomitant solute deficits and ongoing solute losses should also be replaced as appropriate. If hypernatremia is caused only by pure water loss, free water can be administered as 5% dextrose in water. Half-normal saline or quarter-normal saline is used if a sodium deficit is also present. In patients with hypotension or shock, the effective arterial blood volume should be restored with normal saline or colloids before the plasma tonicity is corrected.

CLINICAL USE OF DIURETICS

Diuretics reduce sodium and chloride reabsorption in the renal tubules, thereby increasing urine volume. Enhanced solute and fluid excretion can be initiated through osmotic diuresis or inhibition of transport in the kidney tubules. Diuretics are categorized according to the sites within the kidney tubules where they inhibit sodium reabsorption (see Chapter 9, Essential Hypertension, and Chapter 28, Chronic Kidney Diseases).

Loop Diuretics

The loop diuretics—furosemide, bumetanide, torsemide, and ethacrynic acid—are the most potent diuretics available. They are also known as high-ceiling diuretics because they can inhibit the reabsorption of up to 20% to 25% of the filtered sodium load. The loop diuretics act in the medullary and cortical portion of the thick ascending limb of Henle's loop. Sodium and chloride transport through the $Na^+/K^+/2Cl^-$ carrier in the luminal membrane is inhibited. Reabsorption of calcium and magnesium is reduced secondary to the reduction in sodium chloride transport. The loop diuretics also possess a vasodilatory effect that can contribute to their diuretic activity.

Thiazide Diuretics

The thiazide diuretics are a group of structurally similar compounds that share a common mechanism of action. Several other sulfonamide diuretics that differ chemically, such as chlorthalidone, indapamide, and metolazone, also have diuretic effects similar to the thiazides. The primary site of action of these diuretics is at the proximal portion of the distal tubule. Sodium reabsorption via the Na^+/Cl^- cotransporter is blocked through competition with the chloride site of the transporter. Some of these agents, such as chlorothiazide, may also reduce sodium transport in the proximal tubule. The contribution of this effect toward net diuresis is negligible, however, because the sodium ions that are not reabsorbed in the proximal tubule will subsequently be reabsorbed in Henle's loop. Thiazide diuretics can enhance the reabsorption of calcium ion through a direct action on the early distal tubule. Therefore, these agents are useful to reduce calciuria in patients with kidney stones. In contrast, magnesium excretion is increased by the thiazides, which may result in hypomagnesemia.

Potassium-Sparing Diuretics

SPIRONOLACTONE, TRIAMTERENE, AND AMILORIDE

Spironolactone, triamterene, and amiloride are potassium-sparing diuretics that inhibit sodium reabsorption in the cortical collecting tubules through different mechanisms. Spironolactone is a competitive receptor-site antagonist of aldosterone in the distal

---

segment of the renal tubule and is indicated especially for patients with hyperaldosteronism secondary to decreased renal perfusion. Patients with hyperaldosteronism can be identified by urinary electrolyte screening, which shows high urine potassium excretion with concomitant diminished or absent urine sodium excretion. By serving as an aldosterone antagonist, spironolactone inhibits sodium reabsorption and decreases the excretion of potassium and hydrogen ions. Dosages as high as 200 to 400 mg/day may be needed to induce natriuresis in patients with hyperaldosteronism.

In contrast to spironolactone, triamterene and amiloride reduce the passage of sodium ions through the luminal membrane, independent of aldosterone activity, by directly acting on sodium and potassium transport processes in the distal renal tubular cells. Triamterene and amiloride offer the advantage of a more rapid onset of action than spironolactone.

The initial effects of spironolactone are usually delayed for 2 or 3 days, and several additional days are needed to attain maximal diuretic effect. This delay is caused partly by the formation of an active metabolite, canrenone, which accounts for approximately 70% of the antimineralocorticoid activity of spironolactone. The elimination half-life of canrenone is 13.5 to 24 hours in normal subjects and is prolonged in patients with chronic liver disease (59 hours [range, 32–105 hours]) or HF (37 hours [range, 19–48 hours]).[106] Although the elimination half-life of canrenone is prolonged in these patients, plasma canrenone concentrations do not differ significantly from those in normal subjects because assay methods for canrenone are nonspecific and include measurement of both active and inactive metabolites.[107,108]

Triamterene is absorbed incompletely from the GI tract. The drug has a short half-life of 1.5 to 2.5 hours. The total body clearance is high because of rapid and extensive hepatic metabolism. Both the parent compound and the metabolite undergo biliary and renal excretion. As with spironolactone, the hepatic metabolism of triamterene can be altered in patients with cirrhosis.[109] The diuretic effect of triamterene begins within 2 to 3 hours of administration, with a maximal duration of 12 to 16 hours.

Amiloride does not undergo hepatic metabolism; approximately 50% of amiloride is excreted in the urine unchanged and the remainder is recovered in the stool as unabsorbed drug or through biliary excretion. Serum amiloride concentrations peak 3 hours after oral ingestion, and the half-life is 6 hours. Although commonly administered doses are in the range of 2.5 to 10 mg, diuresis increases over a much greater range. The onset of action is 2 hours, with maximal effects at 4 to 6 hours. Duration of action is dose dependent and ranges from 10 to 24 hours. Amiloride does not undergo hepatic metabolism, and the drug can accumulate in patients with renal insufficiency.

The maximal amount of filtered sodium that can be excreted through the action of potassium-sparing diuretics is approximately 1% to 2%. Their natriuretic activity, therefore, is relatively limited compared with the thiazide and loop diuretics. These agents are often used concurrently with thiazide and loop diuretics to reduce potassium loss. Spironolactone is especially useful in patients with liver cirrhosis and ascites, who are likely to have high levels of aldosterone.

Acetazolamide

Acetazolamide inhibits carbonic anhydrase, an enzyme that mediates the excretion of sodium, bicarbonate, and chloride ions in the proximal tubule. Use of the drug will increase urine pH owing to the increased excretion of bicarbonate ion. The net diuretic and natriuretic effects are limited, similar to those of the potassium-sparing diuretics. Because of the drug's proximal site of action, the sodium ions that are not reabsorbed will subsequently be reclaimed in Henle's loop and the distal tubule. In addition, metabolic acidosis associated with the use of acetazolamide diminishes its diuretic effect.

Osmotic Diuretics

Osmotic diuretics are nonresorbable solutes in the kidney tubule. They act primarily in the proximal tubule, where the osmotic pressure they generate impedes the reabsorption of water and solutes. Unlike other diuretics, the amount of water loss exceeds the concurrent loss of sodium and potassium. Mannitol has been used in the early treatment of oliguric postischemic acute renal failure to increase urine output. Urea, another osmotic diuretic, and mannitol are used to reduce intracranial pressure through cellular dehydration.

Complications of Diuretic Therapy

Disturbances in fluid, electrolyte, and acid–base balance are common side effects associated with diuretic therapy. These side effects, including hypokalemia, are discussed in detail in Chapter 9, Essential Hypertension; Chapter 14, Heart Failure; and Chapter 45, Gout and Hyperuricemia. Two complications, hyponatremia and metabolic alkalosis and acidosis, are, however, discussed in the subsequent section because of their specific relevance to fluid balance.

HYPONATREMIA

Thiazides induce diuresis by inhibiting sodium and water reabsorption in the kidney tubule. Because both sodium and water are lost, overdiuresis per se is not expected to cause hyponatremia. Instead, hyponatremia represents a dilution of plasma sodium by excess free water caused by volume-depletion–induced ADH activity. The enhanced ADH secretion increases free-water reabsorption, resulting in hyponatremia. Large doses of diuretic, excessive water drinking, and severe sodium-intake restriction all will accentuate the hyponatremia. Elderly patients are particularly susceptible to this diuretic-induced complication because of the age-associated loss of nephrons and consequent impairment of sodium–potassium exchange.

METABOLIC ALKALOSIS AND ACIDOSIS

Metabolic alkalosis often occurs in conjunction with potassium depletion secondary to diuretic use. The diuretic-induced contraction of ECF volume stimulates the secretion of aldosterone, which promotes the absorption of sodium and the retention of hydrogen ions in the kidney tubule. The net urinary loss of hydrogen ions into the urine results in metabolic alkalosis. Generally, reducing the dose of the diuretic will restore the acid–base balance.

Acetazolamide causes metabolic acidosis by inhibiting carbonic anhydrase, which results in urinary excretion of sodium bicarbonate. Spironolactone, amiloride, and triamterene can cause hyperchloremic metabolic acidosis because of their ability to decrease potassium and hydrogen ion tubular secretion. Patients with renal dysfunction or those taking potassium supplements or angiotensin-converting enzyme inhibitors, which reduce aldosterone secretion, are at increased risk for developing hyperkalemia and metabolic acidosis.

POTASSIUM

Homeostasis

The total amount of potassium stored in the body is approximately 45 to 55 mEq/kg and varies with age, sex, and muscle mass. Lower total body potassium is found in older adults, females, and individuals

---

with a low lean-body-mass to fat ratio. Potassium is distributed unevenly between the intracellular and extracellular compartments; 98% of the total body potassium resides in the intracellular compartment, predominantly the muscle, and only 2% is found in the extracellular space.[34,110] The disproportionate intracellular distribution of potassium is maintained by the Na^+/K^+ ATPase pump, which transports sodium out of the cell in exchange for potassium.[110–113] The cell membrane resting potential is determined by the ratio of intracellular/extracellular potassium concentrations. As this ratio increases, hyperpolarization of the cell membrane occurs. Conversely, cellular depolarization results when the ratio decreases. In both situations, generation of the action potential is impaired.

The plasma potassium concentration is maintained within a narrow range of 3.5 to 5.0 mEq/L. Although the plasma potassium concentration can be affected by the total body potassium store, total body potassium excess or deficit cannot be estimated accurately based solely on the plasma concentration. In fact, a normal plasma potassium concentration does not imply normal total body potassium because multiple factors affect the plasma potassium concentration independent of total body potassium.[111]

Potassium homeostasis is maintained by both renal and extrarenal processes. The renal process regulates total body potassium by matching potassium excretion to dietary intake (external balance),[114] whereas the extrarenal process regulates potassium distribution across cell membrane (internal potassium balance).[111–112]

The normal daily intake of potassium ranges between 50 and 100 mEq. Approximately 90% of the ingested potassium is eliminated by the kidneys and approximately 10% is eliminated via the GI tract.[114] Potassium is filtered freely through the glomerulus and then reabsorbed. By the time the filtrate reaches the distal convoluted tubule, greater than 90% of filtered potassium has already been reabsorbed. The amount of potassium excreted is determined by distal tubular potassium secretion in the principal cells of the cortical collecting duct, which is under the influence of aldosterone. Hyperkalemia, increased potassium load, and AT_2 can all stimulate aldosterone secretion.[111]

Factors that affect renal potassium excretion include tubular flow, sodium delivery to the distal segments of the nephron, the presence of poorly absorbable anions that increase luminal electronegativity, acid–base status, and aldosterone activity.[114] Potassium excretion increases during hyperkalemia and decreases during potassium depletion. Excretion of an acute potassium load is a slow process, with only half the potassium load excreted in the first 4 to 6 hours. Lethal hyperkalemia would ensue were it not for the extrarenal process that regulates intracellular/extracellular potassium distribution.[111]

The Na^+/K^+ ATPase pump, which extrudes sodium from the cell in exchange for potassium, is pivotal in maintaining internal potassium balance.[114] Different hormonal factors regulate the activity of the Na^+/K^+ ATPase pump, namely insulin, catecholamines, and aldosterone. Insulin, the most important regulator, enhances potassium uptake by muscle, liver, and adipose tissue by stimulating Na^+/K^+ ATPase.[115] Indeed, basal insulin secretion is essential for potassium homeostasis.[111] Whereas β_2-adrenergic agonists activate the Na^+/K^+ ATPase pump via cyclic adenosine monophosphate and cause hypokalemia, α-adrenergic stimulation promotes hepatic potassium release and causes hyperkalemia.[116] Epinephrine, an α-agonist and β-agonist, causes a transient increase in plasma potassium (α-agonism) followed by a more sustained decrease in plasma potassium (β-agonism).[116,117] Besides its kaliuretic effect and enhanced potassium secretion in the colon, aldosterone also stimulates Na^+/K^+ ATPase.

Other factors that affect the transcellular distribution of potassium include systemic pH, plasma tonicity, and exercise.[111,113] The effect of acid–base balance on potassium distribution is not readily predictable and depends on both the nature and the direction of the underlying disorder. The concomitant effect of the acid–base disorder on renal potassium excretion further complicates the relationship between plasma potassium concentration and pH.[111,118] In acute inorganic acidosis, plasma potassium concentration increases by 0.2 to 1.7 mEq/L per 0.1-unit decrease in pH. Chronic inorganic metabolic acidosis usually is associated, however, with hypokalemia because of urinary potassium loss associated with both proximal (type 2) and distal (type 1) renal tubular acidosis.[111,118] In contrast, organic acidosis commonly has no effect on potassium distribution.[119]

Other associated factors in organic acidosis may, however, affect cellular potassium distribution.[118] For example, hyperglycemia in diabetic ketoacidosis may increase the serum potassium concentration because of the hypertonic effect of glucose.[120] Hypertonicity causes cell shrinkage and increases the intracellular to ECF potassium gradient, favoring potassium egress. Acute metabolic alkalosis only modestly decreases the plasma potassium concentration: 0.3 mEq/L for each 0.1-unit pH increment.[111,118] As with chronic metabolic acidosis, chronic metabolic alkalosis causes profound renal potassium wasting and is associated with hypokalemia. Respiratory acid–base disorders usually are associated with less significant changes in plasma potassium concentration than are metabolic acid–base disorders.[118] Exercise often causes an increase in the serum potassium concentration to a degree that varies with the intensity of the exercise.[121]

Hypokalemia

ETIOLOGY

CASE 27-8

QUESTION 1: J.P., a 60-year-old woman, presents to the ED with complaints of malaise, generalized weakness, nausea, and vomiting for 3 days. Her medical history includes hypertension for 20 years. J.P.'s current medications include hydrochlorothiazide 25 mg/day and nifedipine XL 30 mg/day. She has not been able to take her medications in the past few days, however, because of vomiting. J.P. denies recent diarrhea or use of laxatives. Her BP is 130/70 mm Hg with a pulse of 80 beats/minute while sitting, and 120/70 mm Hg with a pulse of 95 beats/minute on standing. Physical examination reveals a thin, older woman with poor skin turgor, dry mucous membranes, and a flat jugular vein. T-wave flattening is noted on the electrocardiogram (ECG). Laboratory tests show the following:

Serum Na, 138 mEq/L
K, 2.1 mEq/L
Cl, 100 mEq/L
Bicarbonate, 32 mEq/L
BUN, 30 mg/dL
Creatinine, 1.2 mg/dL
Glucose, 100 mg/dL

ABG shows pH, 7.50; PCO_2, 45 mm Hg; and PO_2, 70 mm Hg at room air. Urine electrolytes are sodium, 30 mEq/L; potassium, 60 mEq/L; and chloride, less than 15 mEq/L. The patient's presentation is consistent with gastroenteritis. What are the causes of J.P.'s hypokalemia?

When evaluating hypokalemia, the clinician should determine whether the hypokalemia is a result of low intake, increased cellular uptake of potassium, or excessive loss of potassium via the kidneys, GI tract, or skin.[34,122] History and physical evidence of potassium depletion, medication history (including use of over-the-counter medicines), and assessment of the patient's BP, extracellular volume, and concurrent acid–base status can provide clues to the causes of hypokalemia.[34,122]

Because J.P. has been unable to eat for the past few days, decreased oral intake may have contributed to her hypokalemia. Because most foods are rich in potassium, however, inadequate intake rarely is the sole cause of potassium depletion unless inappropriate and continued renal or extrarenal losses occur, or potassium intake is severely restricted to less than 10 to 15 mEq/day.[122] Alkalosis,[119] insulin administration,[111] hypertonic solution administration, periodic paralysis,[123] β_2-agonists,[124] barium poisoning,[125] and treatment of megaloblastic anemia with vitamin B_{12}[126] all have been associated with increased cellular potassium uptake (Table 27-2). Although the relationship between the degree of hypokalemia and increase in blood pH varies widely,[118] J.P.'s metabolic alkalosis probably enhances the cellular uptake of potassium. The transcellular shift of potassium should not result in total body potassium depletion, however.

The GI tract is an important site of potassium loss, particularly through vomiting and diarrhea. Because the potassium content of gastric secretion (5–10 mEq/L) is much less than that of the intestinal secretion (up to 90 mEq/L),[122] loss of a large volume of gastric secretion is needed to produce substantial potassium depletion. Potassium deficit induced by vomiting, however, is commonly secondary to renal potassium loss, especially within the initial 24 to 48 hours.[127] The loss of hydrogen ion in gastric juice results in an elevated plasma bicarbonate concentration. The increased amount of bicarbonate ion, as a nonresorbable anion, increases water delivery to the distal nephron and enhances sodium reabsorption and potassium secretion, resulting in hypokalemia. The potassium wasting is often transient, because increased proximal reabsorption of sodium and bicarbonate will result in diminished bicarbonate delivery to the distal site. Reduced potassium excretion will ensue, commonly within 48 to 72 hours. Subsequent potassium loss will then be primarily consequent to gastric secretion removal.

The absence of diarrhea in J.P. excludes the GI tract as the source of potassium loss. Potassium loss through the skin is also unlikely in J.P. because the potassium concentration of sweat is less than 10 mEq/L. Therefore, profuse sweating, such as that induced by vigorous exercise in a hot, humid environment, or severe burns are needed to cause substantial loss.

J.P.'s inappropriately high urinary potassium concentration indicates that the kidney is the source of the potassium loss.[34,122] The urinary potassium concentration is a good marker for differentiating various hypokalemic syndromes. A urinary potassium excretion of less than 20 mEq/day suggests extrarenal potassium loss. Renal potassium wastage cannot be excluded, however, unless the low urinary potassium excretion is accompanied by a sodium intake of at least 100 mEq/day, because a low-sodium diet can reduce renal potassium excretion.[34] In J.P., the metabolic alkalosis and hypovolemia promote renal potassium wastage.[34,122] The distal delivery of a large sodium bicarbonate load and increased aldosterone activity (from hypovolemia) enhance potassium secretion and severely impair the kidney's ability to conserve potassium. The hydrochlorothiazide, which J.P. had been taking until 3 days before admission, could also have induced hypokalemia through volume depletion, hypochloremic metabolic alkalosis, and renal potassium wastage. The diuretic is unlikely, however, to be the cause for J.P.'s hypokalemia because she has stopped taking the medication, and this is reflected by the low urinary chloride concentration.[15] Bartter syndrome, which presents as normotension, hypokalemia, hypochloremic metabolic alkalosis, and renal potassium wastage, is characterized by impaired renal sodium and chloride reabsorption. The low urinary chloride concentration in J.P. can rule out Bartter syndrome. Other causes of hypokalemia are listed in Table 27-2.

In an asymptomatic hypokalemic patient with no apparent causes for potassium depletion or transcellular redistribution, pseudohypokalemia should be excluded before pursuing an intensive evaluation.[106] Spurious hypokalemia can occur in leukemic patients whose leukocyte count ranges from 100,000 to 250,000 cells/μL.[128] The potassium in serum is taken up by the large number of leukemic cells when the blood specimen is allowed to stand at room temperature.

CLINICAL MANIFESTATIONS

CASE 27-8, QUESTION 2: What clinical manifestations of hypokalemia are evident in J.P.?

Table 27-2

Drugs that Most Commonly Induce Hypokalemia

Drug	Mechanism	Predisposing Factors
Acetazolamide	Marked ↑ in renal K+ loss	Most profound with short-term therapy
Amphotericin	Renal K+ loss (renal tubular acidosis)	Concurrent piperacillin, ticarcillin
β_2-Agonists	Intracellular shift of K+	
Cisplatin	Renal K+ loss secondary to renal tubular damage	May be dose related but can occur after a single 50-mg/m^2 dose

Corticosteroids	Renal K+ loss. Enhanced Na+ reabsorption at distal tubule and collecting ducts in exchange for K+ and H+	Supraphysiologic doses of agents with moderate to strong mineralocorticoid activity (e.g., prednisone, hydrocortisone)
Insulin with glucose	Intracellular shift of K+	Predictable effect when insulin administered to patients with diabetic ketoacidosis’ combination used to treat hyperkalemia
Penicillins (piperacillin, ticarcillin)	High Na+ load and nonresorbable anions can ↑ K+ loss	Was more common with carbenicillin when it was available; newer penicillins are used in lower doses; less likely to produce hypokalemia
Thiazide and loop diuretics	Renal K+ loss. ↑ Na+ delivery to the late distal tubule, resulting in Na+ resorption in exchange for K+	Patients with hyperaldosteronism (e.g., cirrhosis, HF) predisposed; may be dose related

HF, heart failure.

The clinical presentation of hypokalemia, which depends on the severity of potassium depletion, is a result of changes in cell membrane polarization.[122] Patients are usually asymptomatic when the plasma potassium level is 3.0 to 3.5 mEq/L, but they may complain of malaise, weakness, fatigue, and myalgia. J.P.’s muscle weakness and ECG changes reflect the muscular and cardiac manifestations of hypokalemia, respectively.[129,130]

Potassium depletion can lead to hyperpolarization of myocardial cells and a prolonged refractory period. When serum potassium concentrations fall below 3 mEq/L, T-wave flattening, straight tubule segment depression, and prominent U waves are seen on the ECG.[130]

Mild hypokalemia (potassium concentration of 3.0–3.5 mEq/L) is potentially arrhythmogenic in patients with underlying coronary artery disease. The incidence of ventricular arrhythmia increases with the degree of hypokalemia. Patients without underlying heart disease may be susceptible to these myocardial effects during exercise, especially if the patient’s pre-exercise potassium concentration is less than 3.5 mEq/L, because the potassium concentration may drop to less than 3.0 mEq/L as a result of β_2-adrenergic receptor-mediated cellular potassium uptake.[122] Potassium depletion may also increase the BP,[123] which can be lowered with potassium supplementation.[131]

When the serum potassium concentration is less than 2.5 to 3.0 mEq/L, muscle weakness, cramps, general malaise, fatigue, restless leg syndrome, and paresthesia can occur, probably because potassium is necessary for vasodilation in skeletal muscle. In addition, severe potassium depletion (<2.5 mEq/L) can result in elevation of serum creatine phosphokinase, aldolase, and aspartate aminotransferase levels. Rhabdomyolysis can ensue when the serum potassium concentration falls below 2.0

mEq/L.[122,129]

Chronic potassium depletion can alter renal function and structure, which can manifest as decreased GFR and renal blood flow, disturbance in tubular sodium handling, impaired urinary concentrating ability with polydipsia, and ADH-resistant nephrogenic diabetes insipidus.[106,115] Reversible pathologic changes include renal hypertrophy and epithelial vacuolization of the proximal convoluted tubule. Interstitial scarring and tubular atrophy have been reported with prolonged potassium depletion.[122]

Other effects of hypokalemia and potassium depletion include decreased insulin secretion resulting in carbohydrate intolerance,[132] metabolic alkalosis, and increased renal ammoniagenesis, which may play a role in the development of hepatic encephalopathy.[133]

TREATMENT

CASE 27-8, QUESTION 3: How should J.P.'s hypokalemia be treated?

J.P.'s protracted vomiting should be corrected, and fluids and electrolytes (sodium, potassium, and chloride) should be replaced to correct the volume deficit, hypokalemia, and hypochloremic metabolic alkalosis. Hydrochlorothiazide should continue to be withheld.

The amount of potassium deficit and the rate of continued potassium loss should be determined to guide replacement therapy. It has been estimated that a 1-mEq/L fall in serum potassium from 4 to 3 mEq/L represents a total body deficit of approximately 200 mEq. When the serum potassium falls to less than 3 mEq/L, the total body deficit increases by 200 to 400 mEq for each 1 mEq/L reduction in serum concentration. Other data suggest that even greater degrees of potassium loss can occur—a deficit of 100 mEq per 0.27-mEq/L fall in the serum potassium concentration.[110] Transcellular redistribution of potassium may, however, significantly alter the relationship between serum concentration and total body deficit.[122] Therefore, potassium repletion should be guided by close monitoring of serum concentrations and analysis of J.P.'s urine for potassium content to help assess the need for additional replacement.

The route of potassium administration depends on the acuity and severity of hypokalemia,[134] but oral supplementation is usually preferred. The parenteral route is indicated for patients who cannot tolerate high dosages of oral potassium supplements and for those with severe or symptomatic hypokalemia. J.P.'s potassium deficit is estimated to be 300 to 500 mEq, but because she is only moderately symptomatic, aggressive therapy is not indicated. Potassium chloride can be added to her IV fluid in a concentration of 40 mEq/L and infused at a rate that does not exceed 10 mEq/hour. For patients with life-threatening, hypokalemia-induced arrhythmias or those with a serum potassium level less than 2.0 mEq/L, a more concentrated potassium solution (60 mEq/L) can be infused at a rate not exceeding 40 mEq/hour. A solution that is too concentrated or a rate of infusion that is too rapid would likely cause phlebitis in the peripheral veins and could cause arrhythmias, especially when administered through a central line. The potassium concentration should be monitored every 4 hours, more frequently in patients with severe potassium depletion or when a rapid infusion is given.[135] ECG monitoring is mandatory to identify life-threatening hyperkalemia that can result from over-correction.

Parenteral potassium can be given as chloride, acetate, or phosphate. The chloride salt is preferred in J.P., who has concurrent hypochloremic metabolic alkalosis. The acetate preparation is useful in cases of concomitant metabolic acidosis. Potassium phosphate is indicated if hypophosphatemia coexists. In the latter condition, the serum calcium concentration should also be monitored because hypocalcemia may ensue. Glucose solution should be avoided as the vehicle because glucose-induced insulin secretion will promote intracellular potassium uptake.[136]

Once J.P.'s potassium levels are replenished and she can take medicine by mouth, oral potassium chloride can be started (see Chapter 9, Essential Hypertension, and Chapter 14, Heart Failure).

Hyperkalemia

ETIOLOGY

CASE 27-9

QUESTION 1: A.B., a 25-year-old woman with type 1 diabetes and hypertension, returns to the clinic for follow-up. Her BP is 170/90 mm Hg with a pulse of 80 beats/minute, and her physical examination is remarkable for 2+ pedal edema. Laboratory tests show the following:

Plasma Na, 135 mEq/L
K, 5.8 mEq/L
Cl, 108 mEq/L
Total CO_2, 20 mEq/L
BUN, 28 mg/dL
Creatinine, 2 mg/dL
Glucose, 200 mg/dL

Current medications include oral captopril 25 mg 3 times daily, hydrochlorothiazide 25 mg/triamterene 37.5 mg one capsule daily, human isophane insulin 30 units subcutaneously (SC) every morning, and ibuprofen 200 mg as needed for menstrual cramps. She uses a salt substitute occasionally. What is the etiology of her hyperkalemia?

Before conducting any extensive evaluation to identify the etiology of hyperkalemia, the serum potassium concentration ought to be repeated to confirm the presence of hyperkalemia. Also to be ruled out are the different causes of spurious hyperkalemia, which can result from severe leukocytosis (>500,000/μL),[136] thrombocytosis (>750,000/μL),[137] or hemolysis within the blood collection tube.[138] Pseudohyperkalemia is a test-tube phenomenon that occurs when potassium is released from leukocytes, platelets, or erythrocytes during blood coagulation. These disorders can be confirmed easily by comparing serum (clotted) and plasma (unclotted) potassium concentrations from the same blood sample. The two values should agree within 0.2 to 0.3 mEq/L. Improper tourniquet technique, causing strangulation of the patient's arm before blood sampling, may also result in spurious hyperkalemia.[139]

Identifying the etiology of hyperkalemia can be approached systematically by considering possible disturbances in internal and external potassium balance. The former involves transcellular flux of potassium from the intracellular to the extracellular space, whereas the latter involves either increased intake, including increased endogenous potassium load (e.g., rhabdomyolysis,[140] tumor lysis syndrome[141]), or decreased elimination. A thorough medication history is important to identify drugs associated with hyperkalemia.[142–144] (Also see Chapter 28, Chronic Kidney Diseases, for additional information on hyperkalemia.)

A dietary history should ascertain whether A.B.'s consumption of potassium-rich foods, salt substitutes, or potassium supplements has increased. Dietary intake alone will not induce hyperkalemia unless renal excretion is impaired. Usually, the GFR must be less than 10 to 15 mL/minute, unless there is concurrent hypoaldosteronism or distal tubular potassium secretory defects.[1] A.B.'s renal insufficiency is mild, with an estimated CrCl of 40 mL/minute.

Conditions associated with low renin and aldosterone, which usually present as hyperkalemia and hyperchloremic metabolic acidosis, decrease potassium excretion by the kidneys. These include diabetes,[145] obstructive uropathy, sickle cell disease, lupus nephritis, and various tubulointerstitial diseases (e.g., gouty nephropathy, analgesic nephropathy). Adrenal insufficiency presents commonly with hyperkalemia because of mineralocorticoid deficiency.[146] A.B.'s hyperglycemia because of poorly controlled diabetes may cause movement of potassium-rich fluid from the intracellular space to the extracellular space because of the increased tonicity. Elevating the plasma tonicity by 15 to 20 mOsm/kg will increase the plasma potassium concentration by 0.8 mEq/L.[147] Patients with diabetes, mineralocorticoid deficiency, or end-stage renal failure, which commonly results in hyporeninemic hypoaldosteronism, are particularly susceptible.

A.B. is also taking several medications that may impair her ability to excrete potassium. Captopril indirectly decreases aldosterone secretion by decreasing the formation of AT_2.[148] Ibuprofen inhibits prostaglandin production as well as renin and aldosterone secretion.[149] Other drugs that cause hyperkalemia by impairing renin and aldosterone production include AT_2 receptor antagonists,[150] β-adrenergic blockers,[151] lithium,[152] heparin,[153,154] and pentamidine.[155] Triamterene, a component of her diuretic, inhibits tubular potassium secretion, as do amiloride, spironolactone, high-dose trimethoprim,[156,157] cyclosporine,[158] tacrolimus,[159] and digitalis preparations.[160] By inhibiting Na^+/K^+ ATPase, digitalis decreases tubular potassium secretion and reduces cellular potassium uptake. Arginine,[161] succinylcholine,[162] β-adrenergic blockers, α-adrenergic agonists, and hypertonic solutions also cause hyperkalemia by impairing transcellular potassium distribution into the intracellular space.

CLINICAL MANIFESTATIONS

CASE 27-10

QUESTION 1: V.C., a 44-year-old woman with chronic renal failure, returns to the outpatient unit for routine hemodialysis with complaints of severe muscle weakness. Her vital signs are BP, 120/80 mm Hg; pulse, 90 beats/minute; RR, 20 breaths/minute; and temperature, 98°F. Laboratory data are as follows:

Serum K, 8.9 mEq/L
Total CO_2, 15 mEq/L
BUN, 60 mg/dL
Creatinine, 9 mg/dL
Glucose, 100 mg/dL

The ECG reveals an increased PR interval and a widened QRS complex. What clinical manifestations of hyperkalemia are evident in V.C.?

Hyperkalemia decreases the intracellular/extracellular potassium ratio. Hence, the resting membrane potential becomes less negative and moves closer to the threshold excitation potential. Muscle weakness and flaccid paralysis result when the resting membrane potential approaches the threshold potential, rendering the excitable cells unable to sustain an action potential.

The cardiac toxicity of hyperkalemia is a major cause of morbidity and mortality, with ECG findings paralleling the degree of hyperkalemia. When plasma potassium is greater than 5.5 to 6.0 mEq/L, narrow, peaked T waves and a shortened QT interval are seen. As the plasma potassium concentration increases further, the QRS complex widens and the P-wave amplitude decreases. As the level reaches 8 mEq/L, the P wave disappears and the QRS complex continues to widen and merge with the T wave to form a sine wave pattern. If these ECG changes are not recognized and no treatment is initiated, ventricular fibrillation and asystole will ensue. Hyponatremia, hypocalcemia, and hypomagnesemia all reduce the threshold potential, thereby increasing the patient's susceptibility to the cardiac effects of hyperkalemia.[140] V.C.'s muscle weakness, ECG, chronic renal failure, and serum potassium concentration all are consistent with severe hyperkalemia.

TREATMENT

CASE 27-10, QUESTION 2: How should V.C.'s hyperkalemia be treated?

Hyperkalemia with ECG changes requires urgent treatment. Three therapeutic modalities are available: (a) agents that antagonize the cardiac effects of hyperkalemia, (b) agents that shift potassium from the extracellular into the intracellular space, and (c) agents that enhance potassium elimination. Considering V.C.'s severe ECG changes, 10% calcium gluconate IV should be administered at a dose of 10 to 20 mL over the course of 1 to 3 minutes. Calcium counteracts the depolarizing effect of hyperkalemia by increasing the threshold potential, thus making it less negative and moving it away from the resting potential. The onset of action occurs in a few minutes, but the effect is short-lived, lasting approximately 15 to 60 minutes. The dose can be repeated in 5 minutes if ECG changes do not resolve and as needed afterward for recurrence. With no response after the second dose, additional attempts, however, are not beneficial. When the hyperkalemia presents with a digitalis overdose, calcium should be used cautiously because it can worsen the cardiotoxic effects of digoxin.[140,163]

Because the serum potassium concentration is not affected by calcium administration, maneuvers should be used to shift potassium from plasma into the cells. Three modalities are available: insulin and glucose, β_2-agonists, and sodium bicarbonate.

Insulin rapidly shifts potassium into the cell in a dose-dependent fashion. The maximal effect occurs at insulin concentrations greater than 20 to 40 times the basal levels. Therefore, endogenous insulin secreted in response to dextrose administration is insufficient, and exogenous insulin must be administered.[111] Although high concentrations of dextrose may worsen hyperkalemia, particularly in diabetic patients because intracellular potassium may be shifted to the extracellular space owing to the elevated plasma tonicity,[164] it is always administered with insulin to prevent hypoglycemia. Regular insulin (5–10 units) can be given with 50 mL of 50% dextrose as IV boluses, followed by a continuous infusion of 10% dextrose at 50 mL/hour to prevent late hypoglycemia.[111] In dialysis patients susceptible to experiencing fasting hyperkalemia, 20 units of insulin can be added to 1 L of 10% dextrose and administered at a rate of 50 mL/hour to prevent the hyperkalemia.[165] The insulin–dextrose combination lowers serum potassium by direct stimulation of cellular potassium uptake and potentiates the potassium-lowering effect of β-adrenergic stimuation.[165] The reduction in potassium is apparent 15 to 30 minutes after the start of the therapy and persists for 4 to 6 hours.[140] In a diabetic patient who is both hyperkalemic and hyperglycemic, insulin alone may be insufficient. If the patient has end-stage renal disease, the insulin–glucose combination is more predictable in lowering plasma potassium concentrations than sodium bicarbonate.[110,163,165]

β_2-Agonists, by binding with the β_2-adrenoreceptor to activate adenylate cyclase, have an additive effect with the insulin–dextrose combination in decreasing serum potassium. When albuterol nebulization is used alone, the hypokalemic effect may be inconsistent.[166] Although side effects of albuterol nebulization are minimal, these agents can cause tachycardia and should be used cautiously in patients with underlying coronary artery disease.[167] Although not commercially available, IV albuterol has a faster onset of action (30 vs. 90 minutes).[168] In contrast, nebulization is easier to set up and is less likely to be associated with tachycardia, but multiple doses are often necessary to attain an adequate response. In conjunction with the insulin–dextrose combination, albuterol (20 mg dissolved in 4 mL of saline) can be administered by nebulization and inhaled over the course of 10 minutes to further decrease serum potassium, if necessary.[169]

Although sodium bicarbonate has long been recommended for the acute treatment of hyperkalemia, its efficacy in this setting has been questioned.[110,163] The usual dose, 44 to 50 mEq, is infused slowly over the course of 5 minutes and repeated in 30 minutes when necessary. Alternatively, it can be added to dextrose and saline solution to form an isotonic sodium bicarbonate infusion.[170] The hypokalemic effect is variable and may be delayed up to 4 hours, and it is reportedly ineffective in patients on maintenance hemodialysis. Although bicarbonate therapy is not a reliable option in the acute management of hyperkalemia, it may be beneficial in patients with severe metabolic acidosis ($pH < 7.20$).[110] Potential complications of sodium bicarbonate therapy are volume overload and metabolic alkalosis.

The definitive treatment of hyperkalemia is removal of potassium from the body. Sodium polystyrene sulfonate (SPS) with sorbitol is an ion-exchange resin that binds potassium in the bowel and enhances its excretion in the stools.[171] Each gram of SPS exchanges 0.5 to 1.0 mmol of potassium for an equal amount of sodium. SPS can be administered orally or rectally; the latter route is preferred in the symptomatic hyperkalemic patient because intestinal potassium exchange occurs mainly in the ileum and colon. A dose of 50 g of SPS in sorbitol can be given as an enema, retained for at least 30 to 60 minutes, at 4-hour to 6-hour intervals. For nonemergent removal of body potassium, 15 to 60 g of SPS with sorbitol suspension can be given orally, which can be repeated as needed. The onset of action is approximately 1 to 2 hours after administration. The major side effects are GI intolerance, including constipation, diarrhea, and sodium overload. Potentially fatal intestinal necrosis, though rare, have been reported with the use of SPS with sorbitol.[172] It is unclear if intestinal injury is caused by SPS or sorbitol, but FDA has released a safety warning against the use of SPS in individuals with impaired bowel function.[173]

Hemodialysis is the most efficient way to remove potassium; potassium clearance by peritoneal dialysis is lower than for hemodialysis.[174] The hypokalemic effect is immediate and lasts for the duration of dialysis[163]; however, the amount of potassium removed is variable.[175] Dialysis with a glucose-free dialysate will remove 30% more potassium than one containing 200 mg/dL of glucose.[176] Table 27-3 summarizes the treatment alternatives for hyperkalemia. Although V.C. is receiving chronic maintenance hemodialysis, the severe cardiac effects of hyperkalemia she experienced warrant immediate institution of the aforementioned measures while awaiting preparation for dialysis. Loop diuretics, which enhance kaliuresis, are rarely useful in managing severe hyperkalemia, especially in patients with renal dysfunction.

Two new oral agents, patiromer and sodium zirconium cyclosilicate, currently still under investigation, have been shown to be effective in reducing serum potassium concentrations in patients with mild-to-moderate hyperkalemia.[177,178] As the studies conducted thus far are short-term studies and excluded patients with severe hyperkalemia, the long-term beneficial and adverse effects of these agents need to be further evaluated.

After V.C.'s condition stabilized, she admitted to eating a lot of fruits in the past few days. Because noncompliance with dietary potassium restriction is the most common cause for acute and chronic hyperkalemia in a dialysis patient, V.C. should be counseled to consume potassium-rich foods in moderation. Medications that impair V.C.'s extrarenal potassium handling should be avoided. If V.C. remains chronically hyperkalemic, SPS will then be needed, probably 3 or 4 times weekly. If hyperkalemia is associated with metabolic acidosis, however, an alkalinizing agent should be added to maintain a serum bicarbonate concentration of about 24 mEq/L.

CALCIUM

Homeostasis

Healthy adults have approximately 1,400 g of calcium in the body, of which greater than 99% is stored in bone. Nonetheless, the 0.1% of the total body calcium that is in the plasma and extravascular fluid plays a critical role in many physiologic and metabolic processes. Calcium is important in maintaining nerve tissue excitability and muscle contractility. It regulates the secretory activities of exocrine and endocrine glands and serves as a cofactor for enzyme systems and the coagulation cascade. It is also an essential component of bone metabolism.

Plasma calcium concentration is normally maintained within a relatively narrow range: 8.5 to 10.5 mg/dL. This is accomplished through a complex interaction between parathyroid hormone (PTH), vitamin D, and calcitonin, as well as the effect of these hormones on calcium metabolism in bone, the GI tract, and the kidneys.

Normally, about 40% of the plasma calcium is protein-bound, primarily to albumin, and is nondiffusible.[126] Of the 60% that is diffusible, about 13% is complexed to various small ligands: phosphate, citrate, and sulfate. The remaining 47% is ionized, free, and physiologically active. Changes in serum protein concentration will alter the concentrations of both protein-bound and total calcium. Therefore, the serum albumin concentration needs to be monitored to adequately interpret the total serum calcium concentration. Each 1-g/dL increase in serum albumin concentration is expected to increase the protein-bound calcium by 0.8 mg/dL, thus increasing the total serum calcium concentration by the same amount. The total serum calcium therefore can be corrected by the following equation:

Table 27-3

Treatment of Hyperkalemia

Drug	Mechanism	Dose	Comment
Calcium gluconate	Reverse cardiotoxicity caused by K+	10 to 20 mL 10% calcium gluconate IV over 1 to 3 minutes; may repeat once	Onset: 1 to 3 minutes Duration: 30 to 60 minutes. (K+) remains unchanged
Insulin and glucose	Redistribution of K+ intracellularly	5 to 10 units regular insulin with 50 mL 50% dextrose, then $D_{10}W$ infused at 50 mL/hour[a]	Onset: 15 to 30 minutes Duration: several hours Watch for hypoglycemia and hypokalemia. Does not ↓ total body K+
β_2-agonists (e.g., albuterol)	Redistribution of K+ intracellularly	Oral: 2 or 4 mg TID–QID Inhalation: 20 mg in 4 mL saline via nebulizer	Onset: 30 to 60 minutes Duration: 2 hours
SPS	Cationic binding resin. 1 g of resin binds 0.5 to 1 mEq K+ in exchange for Na+	Oral: 15 to 20 g with 20 to 100 mL 70% sorbitol every 4 to 6 hours; PRN preferred Retention enema: 50 g in 50 mL (70% sorbitol and 150 mL H_2O). Retain 30 minutes and follow with nonsaline irrigation	Onset: Slow; 50 g will lower (K+) by 0.5 to 1 mEq/L over 4 to 6 hours; watch for Na+ overload (100 mg Na+/1 g SPS)
$NaHCO_3$	Redistribution of K+ intracellularly	50 mEq IV for 5 minutes. Repeat PRN	Onset: variable, ≈30 minutes May work best in acidosis Watch for Na+ overload and hyperosmolar state No change in total body K+
Dialysis	Removal of K+		Use as last resort

[a] Glucose unnecessary in patients with high glucose concentrations.

BID, twice daily; IV, intravenous; PRN, as needed; QID, 4 times daily; SPS, sodium polystyrene sulfonate; TID, 3 times daily.

$$\text{Correct Ca} = \text{Observed Ca} + 0.8\,(\text{Normal albumin} - \text{Observed albumin}) \qquad \text{(Eq. 27-13)}$$

where normal albumin = 4 g/dL.

Calcium is also bound to plasma globulins at the rate of 0.16 mg of calcium for each gram of globulin. When the total globulin concentration exceeds 6 g/dL, moderate hypercalcemia may be seen. Changes in pH have an effect on calcium protein-binding; acidosis decreases calcium binding, resulting in an increase in free-calcium fraction, whereas an increase in pH reduces the amount of ionized calcium. Changes in serum phosphate and sulfate concentrations are expected to alter the fraction of ionized calcium because of the formation of calcium complexes with these anions. The presence of abnormal plasma proteins with a high affinity for calcium-binding, as in patients with multiple myeloma, also affects the preceding equation for serum calcium concentration correction.[179]

Serum calcium concentration is regulated by the combined effect of GI absorption and secretion, renal reabsorption, and turnover of the skeletal calcium pool. Several hormones, such as PTH, 1,25-dihydroxyvitamin D_3, and calcitonin, have significant effects on these processes. Balanced diets generally contain 600 to 1,000 mg of calcium, although the minimum daily requirement is 400 to 500 mg. Calcium is primarily absorbed in the duodenum and jejunum via saturable and nonsaturable processes.[180] The nonsaturable process is diffusive in nature and varies with luminal calcium concentration. The saturable carrier-mediated component is stimulated by 1,25-dihydroxyvitamin D_3. Absorption of calcium is enhanced when the calcium intake is low and also when the demand is increased, such as in pregnancy and when total body calcium is depleted. Conversely, protein deficiency can reduce intestinal calcium absorption, presumably because of the reduced amount of specific calcium-binding protein.[181] Calcium is also secreted into the bowel lumen, which may account for the presence of a negative calcium balance when there is no oral calcium intake.[182]

The portion of plasma calcium that is not bound to protein is filtered by the glomerulus. Approximately 97% to 99.5% of the filtered calcium is reabsorbed: 60% in the proximal tubule, 20% in the ascending limb, 10% in the distal tubule, and 3% to 10% in the collecting duct. Approximately 20% of the calcium in the kidney tubule is ionized, whereas the remainder is bound to anions such as citrate, sulfate, phosphate, and gluconate. The extent of calcium reabsorption depends on the presence of specific anions and also on the urine pH, which affects the fraction of calcium bound to anions. Passive reabsorption at the proximal convoluted tubule is linked closely to sodium transport and is increased by ECF contraction and decreased by volume expansion. At the proximal straight tubule, the transport process is active and dissociable from sodium and water transport. PTH increases the calcium reabsorption at the distal tubule and also at the collecting duct independent of sodium reabsorption. Acidosis can also increase renal calcium excretion by inhibiting tubular reabsorption and by increasing the ultrafiltrable calcium through reduced binding of calcium to plasma proteins. Conversely, alkalosis promotes calcium protein binding, thus reducing the amount of ultrafiltrable calcium. It also induces hypocalciuria independent of PTH. Phosphorus administration reduces renal calcium excretion, whereas phosphorus depletion increases urinary calcium elimination. Normally, approximately 50 to 300 mg of calcium is excreted by the kidneys daily, but this can be increased to 600 mg/day.[183]

The other important factor regulating plasma calcium concentration is bone metabolism. The rate of bone turnover and calcium resorption is influenced by PTH, 1,25-dihydroxyvitamin D_3, and calcitonin.

Hypercalcemia

ETIOLOGY

CASE 27-11

QUESTION 1: A.C., a 62-year-old woman, is brought to the hospital by family members because she has become increasingly lethargic and unresponsive during the past several days. Approximately 4 years ago she underwent a radical mastectomy and node dissection followed by radiation and chemotherapy for breast carcinoma. Despite several courses of chemotherapy, she developed metastasis to the bone. About 1 week before this admission, A.C. complained of fatigue, muscle weakness, and anorexia. Since then, she has spent most of her time in bed and has had very limited oral intake. Medications taken before admission included hydrochlorothiazide, oral morphine sulfate, and tamoxifen. Physical examination reveals a dehydrated, cachectic woman responsive only to painful stimuli. Vital signs include BP, 100/60 mm Hg, and RR, 16 breaths/minute. Pertinent laboratory values are as follows:

Na, 138 mEq/L
K, 4.5 mEq/L
Cl, 99 mEq/L
CO_2, 33 mEq/L
BUN, 40 mg/dL
Creatinine, 1.2 mg/dL
Calcium, 19 mg/dL
Phosphate, 4.5 mg/dL
Albumin, 3.0 g/dL

The ECG revealed a shortened QT interval. What are the common causes of hypercalcemia? Which of these might be responsible for the hypercalcemia seen in A.C.?

Malignancy

Malignancy and primary hyperparathyroidism are the most common causes of hypercalcemia. Hematologic malignancies, such as multiple myeloma, tend to be responsible for more hypercalcemia than are solid tumors. Cancer of the breast, lung, head and neck, and renal cell carcinoma are solid tumors commonly associated with hypercalcemia. Malignancy can cause paraneoplastic hypercalcemia secondary to bone metastasis, which results in increased bone resorption. Alternatively, patients may exhibit hypercalcemia in the absence of bone metastasis owing to the production of osteolytic humoral factors by the tumor. The mediators secreted may be PTH, PTH-like substances, prostaglandins, cytokines, transforming growth factor-α, and tumor necrosis factor.[184]

Hyperparathyroidism

Hyperparathyroidism is the other common cause of hypercalcemia. Although the etiology of primary hyperparathyroidism is unclear, women tend to experience the condition more frequently, especially in the fourth to sixth decades of life. Approximately 75% of patients have a single adenoma, whereas much smaller percentages of patients have multiglandular disease, hyperplasia, or carcinoma.[184] Other conditions that can result in hypercalcemia include postkidney transplantation, immobilization, vitamin A intoxication, hyperthyroidism, Addison disease, and pheochromocytoma. Hypercalcemia can also occur secondary to increased intestinal calcium absorption because of vitamin D intoxication, sarcoidosis, and other granulomatous diseases. Use of thiazide diuretics, lithium, estrogens, and tamoxifen, as well as excessive calcium ingestion together with alkali (milk-alkali syndrome), may result in hypercalcemia.

A.C.'s breast cancer bone metastasis, volume contraction, and use of hydrochlorothiazide and tamoxifen may all contribute to her hypercalcemia.

CLINICAL MANIFESTATIONS

CASE 27-11, QUESTION 2: How is hypercalcemia manifested in A.C.?

The clinical presentations of hypercalcemia vary substantially among patients, but the severity of the symptoms correlates well with free calcium concentrations.[185] The specific presentation depends on the rate of serum calcium concentration elevation, the presence of malignancy, the PTH concentration, and the patient's age. Concurrent electrolyte and metabolic abnormalities and underlying diseases will also have an effect. Because calcium is an important regulator of many cellular functions, hypercalcemia can produce abnormalities in the neurologic, cardiovascular, pulmonary, renal, GI, and musculoskeletal systems. As seen in A.C., the signs and symptoms can be nonspecific: fatigue, muscle weakness, anorexia, thirst, polyuria, dehydration, and a shortened QT interval on the ECG.

The effect of hypercalcemia on the central nervous system includes lethargy, somnolence, confusion, headache, seizures, cerebellar ataxia, altered personality, acute psychosis, depression, and memory impairment. The neuromuscular manifestations include weakness, myalgia, hyporeflexia or areflexia, and arthralgia.

Symptoms of impaired renal function include polyuria, nocturia, and polydipsia. These may reflect a defective concentrating ability, possibly because of resistance to the effects of ADH.[186] The GFR may be decreased because of afferent arteriolar vasoconstriction, and if hypercalcemia is prolonged, nephrolithiasis, nephrocalcinosis, chronic interstitial nephritis, and renal tubular acidosis may be present. Hypermagnesuria and metabolic alkalosis may also be observed.[183]

Calcium has a positive inotropic effect and reduces heart rate, similar to cardiac glycosides. ECG changes indicative of slow conduction, with prolonged PR and QRS intervals and shortened QT intervals, are commonly seen. In severe hypercalcemia, increased QT intervals, widened T waves, and arrhythmia may be present.[183,187]

The GI symptoms of hypercalcemia are related primarily to the depressive action of calcium on smooth muscle and nerve conduction. Constipation, anorexia, nausea, and vomiting result from reduced GI motility and delayed gastric emptying. Duodenal ulcer can occur because of increased acid and gastrin secretion. Pancreatitis can occur during acute hypercalcemia owing to the blockade of the pancreatic ducts caused by intraductal calcium deposits.[183] Proteolytic enzymes may also be activated by calcium to cause tissue damage. Both ulcer disease and pancreatitis are more common in hypercalcemia associated with primary hyperparathyroidism; they are less likely to be seen in patients with malignancy-induced hypercalcemia.[179]

Treatment

CASE 27-11, QUESTION 3: After vigorous fluid resuscitation with IV saline, combined saline and furosemide diuresis was instituted in A.C. Her serum calcium concentration declined very slowly, prompting the use of calcitonin. Despite initial success, the serum calcium concentration rose to pretreatment values within 24 hours. Higher dosages of calcitonin could have been attempted at this point; however, pamidronate was used instead. Her serum calcium concentration finally stabilized at 8 mg/dL after several days of therapy. What was the rationale for each of these regimens? What other agents are available for hypercalcemia treatment?

Several therapeutic approaches are used to lower serum calcium concentration: increasing urinary calcium excretion, inhibiting release of calcium from bone, reducing intestinal calcium absorption, and enhancing calcium complex formation with chelating agents. The underlying disease that causes the hypercalcemia should also be treated, if possible. The specific treatment used depends on the serum ionized calcium concentration, the presenting signs and symptoms, and the severity and duration of hypercalcemia. Immediate therapy was needed for A.C., who had symptoms consistent with severe hypercalcemia.

Specific interventions are described in the subsequent paragraphs, but as an overview, hydration and diuresis with furosemide generally are the first steps in the acute treatment of hypercalcemia. If these measures fail to reduce the serum calcium concentration adequately, several other agents can be added. Calcitonin provides a rapid onset of hypocalcemic effect, but its duration of action is relatively short. Thus, a bisphosphonate could be used to elicit a longer hypocalcemic response. Gallium nitrate is an alternative, but it is not commonly used. Other agents, such as inorganic phosphates, glucocorticoids, and prostaglandin inhibitors, also have been used to treat hypercalcemia with varying success (Table 27-4).

Hydration and Diuresis

As noted, the first-line emergency treatment for hypercalcemia is hydration and volume expansion. Most patients with hypercalcemia are volume-depleted because of the accompanying polyuria, nausea, and vomiting. Normal saline 1 to 2 L is commonly given to correct the fluid deficit and to expand extracellular volume, which will increase urinary calcium excretion by increasing the GFR and inhibiting calcium reabsorption in the proximal tubule. Because both sodium and calcium are reabsorbed at the same site in the proximal tubule, saline hydration will reduce the reabsorption of both cations simultaneously. A.C. was hypotensive and appeared dehydrated; therefore, saline hydration was used initially to treat the hypercalcemia. In patients who have renal failure or HF, saline hydration and forced diuresis should be avoided.

After adequate volume repletion has been established, IV furosemide can be administered to augment calciuresis. Furosemide blocks the reabsorption of sodium, chloride, and calcium at the thick ascending limb of Henle’s loop. Doses of 80 to 100 mg every 2 to 4 hours can be used until a sufficient decline of the serum calcium concentration is attained.[188] Smaller doses (20–40 mg) commonly are given to avoid the significant loss of fluid and electrolytes caused by the more aggressive regimen. Adequate amounts of sodium, potassium, magnesium, and fluid should be used to replace any therapy-induced electrolyte abnormalities. Fluid balance as well as serum and urine concentrations of these electrolytes must be monitored closely. Urine flow must be maintained and the renal loss of sodium chloride must be replaced to preserve the calciuric effect of furosemide.[189] In A.C., the decline of serum calcium concentration was slow, possibly because of inadequate restoration of plasma volume, replacement of renal sodium loss, or both. More aggressive hydration with adequate sodium replacement ensures that the efficacy of furosemide is not compromised.

Table 27-4

Treatment of Hypercalcemia

Intervention	Dose	Comment
Saline and furosemide	1–2 L NS; then furosemide 80 to 100 mg every 2 to 4 hours. Establish and maintain normovolemia. Other electrolytes as needed.	Saline diuresis and volume expansion depresses $Ca^{2}+$ reabsorption in tubules. Lowers ($Ca^{2}+$) within 24 hours. Treatment of choice in patients without HF or renal failure.

Calcitonin	Four international units/kg SC or IM every 12 hours. ↑ Dose or use another therapy if unresponsive after 24 hours (Max: 8 international units/kg every 6 hours).	Inhibits osteoclast resorption and renal reabsorption of calcium. Preferred second-line agent because it has a rapid onset (6 hours) and is nontoxic. It can be used safely in HF and renal failure. Nausea is the major adverse effect. Tolerance occurs in 24 to 72 hours. Concomitant plicamycin can lead to hypocalcemia. Only the salmon-derived product is available.
Biphosphonates (etidronate, pamidronate)	Etidronate: 7.5 mg/kg IV daily × 3 days over at least 2 hours. Maintenance: 20 mg/kg/day PO. Pamidronate: 60 to 90 mg IV for 4 hours × 1. Repeat in 7 days PRN.	Inhibits osteoclast reabsorption in malignancy state. Efficacy 75% to 100%. Onset 48 hours. Duration, days. Concomitant hydration is imperative. Do not use in renal failure. Adverse effects: ↑ phosphorus, ↑ SCr, N/V (oral).
Zoledronic acid	Doses: 4 mg IV administration for 15 minutes.	Potent effect on bone resorption. Preferred bisphosphonate for hypercalcemia of malignancy. May have promising effects on skeletal complications secondary to bone metastasis.
Gallium nitrate phosphate	100–200 $\mathrm{mg/m^2}$/day infused IV over 24 hours for 5 days (depending on severity of hypercalcemia). If calcium levels return to normal before 5 days, therapy may be discontinued. IV PO^{-}_{4} not recommended PO PO^{-}_{4} gradually titrate to 30 to 60 mmol/day (1–3 g/day in divided doses).	Inhibits bone resorption. Patients should be well hydrated during therapy. A urine output of ~2 L/day should be maintained owing to risk for nephrotoxicity (10%). Inhibits bone resorption; soft tissue calcification. IV onset 24 hours but not drug of choice. Oral agents used for chronic therapy. Contraindicated in renal failure.
Corticosteroids	Prednisone: 60–80 mg/day Hydrocortisone: 5 mg/kg/day IV × 2–3 days.	Impair GI absorption and bone resorption. Onset several days. Best in patients with multiple myeloma, vitamin D intoxication, granulomatous conditions. Can be used in HF, renal failure.
Indomethacin	75–150 mg/day.	Reports of efficacy are mixed.

GI, gastrointestinal; HF, heart failure; IM, intramuscularly; IV, intravenously; NS, normal saline; N/V, nausea and vomiting; PO, orally; PRN, as needed; SC, subcutaneously; SCr, serum creatinine.

Calcitonin

Calcitonin can be used when saline hydration and furosemide diuresis fail to lower serum calcium concentration adequately or when their use is contraindicated. Calcitonin reduces serum calcium concentration by inhibiting osteoclastic bone resorption. It may also increase the renal excretion of calcium and phosphorus. Only the salmon-derived calcitonin product is available in the United States.

The serum calcium concentration is often reduced several hours after calcitonin is administered, and the response may last approximately 6 to 8 hours. The drug is relatively nontoxic compared with organic phosphates and may be used in patients with dehydration, HF, or renal failure.[189] Nausea, vomiting, diarrhea, and facial flushing are the more common side effects; soreness and inflammation at the injection site may also be seen.[184] Because of the potential for developing a hypersensitivity reaction to salmon calcitonin, the manufacturer recommends skin testing with 1 international unit of the salmon calcitonin before the first dose. As seen in A.C., tolerance to the hypocalcemic effect of calcitonin can develop after 24 to 72 hours of therapy. This "escape phenomenon" may be secondary to the altered responsiveness of the hormone receptors and might be prevented by concurrent use of corticosteroids.[190] After long-term therapy, antibodies may develop as well.

The dosage of salmon calcitonin is 4 international units/kg given SC or intramuscularly every 12 hours; the maximal dosage is 8 international units/kg every 6 hours. The hypocalcemic response is often limited, and serum calcium concentration seldom drops to the normal range.[191]

Bisphosphonates

Bisphosphonates are synthetic analogs of pyrophosphate that form stable bonds that are resistant to phosphatase degradation during osteoclast-mediated bone mineralization and resorption. The compounds adsorb to the hydroxyapatite crystals of the bone, inhibiting their growth and dissolution. In addition, the compounds may have a direct effect on osteoclasts. The two distinct pharmacologic classes of bisphosphonates that exist have different mechanisms of action. Etidronate, which does not contain any nitrogen atom, is metabolized to cytotoxic, nonhydrolyzable ATP analogs. In contrast, nitrogen-containing bisphosphonates, such as pamidronate and zoledronic acid, inhibit the prenylation of proteins and have potent inhibitory effects on osteoclast-mediated bone resorption.[192] In addition, they induce apoptosis of osteoclasts as well as certain tumor cells. Further antitumor activities may be mediated through their inhibitory effect on angiogenesis, stimulation of the γ-T-cell fraction in blood, and reduction of cancer cells' adherence to bone matrix. At present, etidronate, pamidronate, and zoledronic acid are approved in the United States for the treatment of hypercalcemia secondary to malignancy.

Etidronate

Etidronate is administered in doses of 7.5 mg/kg for 3 consecutive days by IV infusion over the course of 2 to 4 hours. Response may be seen after 1 to 2 days, and normocalcemia is expected to be attained in most patients, with response sustained for greater than 10 days.[193] Because of the inconvenient dosing schedule as well as variability in its duration of action, other bisphosphonates are now preferred for the treatment of hypercalcemia of malignancy. In addition, etidronate may inhibit bone mineralization, a property not shared by other bisphosphonates.

Pamidronate

Pamidronate is more potent than etidronate as an inhibitor of bone resorption, but it has negligible effect on bone mineralization. For moderate hypercalcemia (albumin-corrected serum calcium concentration of 12.0–13.5 mg/dL), a single dose of 60 to 90 mg of pamidronate is commonly infused over the course of 3 to 4 hours. For severe hypercalcemia (albumin-corrected serum calcium concentration >13.5 mg/dL), the dose is 90 mg. The advantages of pamidronate are that it requires only a single dose and produces a superior response compared with three doses of etidronate.[194]

If the hypercalcemia recurs, the etidronate or the pamidronate regimen may be repeated after an interval of greater than or equal to 7 days. Etidronate (20 mg/kg/day by mouth) may be given to prolong the normocalcemic duration, but nausea and vomiting are common with the oral therapy. Long-term treatment may result in osteomalacia; however, the limited life expectancy of most patients may diminish the significance of this adverse effect.

Etidronate use has resulted in renal failure,[195] which probably is caused by the formation of bisphosphonate–calcium complexes in the serum.[196] Because pamidronate requires a lower molar concentration to produce a comparable hypocalcemic effect, it is less likely to impair renal function. In fact, pamidronate has been given to a limited number of patients with end-stage renal disease without adverse consequence.[196]

Zoledronic Acid

Among the bisphosphonates approved for the treatment of hypercalcemia of malignancy, zoledronic acid has the most potent effect on bone resorption. It is superior to pamidronate with respect to the number of complete responses, time needed to attain calcium normalization, and duration of effect.[197] Because 8-mg doses are not superior to 4-mg dose, 4-mg doses are administered IV over the course of 15 minutes.[198] The drug is well tolerated at 4-mg doses. Zoledronic acid's superior efficacy and convenience of administration make it the preferred bisphosphonate for hypercalcemia of malignancy. Emerging studies show that zoledronic acid may also have promising effects in reducing skeletal complications secondary to bone metastasis associated with breast cancer, prostate cancer, non–small cell lung cancer, and multiple myeloma.[198]

Gallium Nitrate

Gallium is a naturally occurring group IIIa heavy metal. In addition to its antitumor activity and potential for use as a chemotherapeutic agent, it has been shown to be effective in the treatment of moderate-to-severe hypercalcemia of malignancy. Hypocalcemia is induced primarily via the inhibition of bone resorption and reduction in urinary calcium excretion.[199] Several clinical studies have shown the effectiveness of gallium nitrate in the treatment of cancer-related hypercalcemia when compared with agents such as calcitonin and bisphosphonates.[199–203] The recommended dose is 100 to 200 mg/m^2/day as a 24-hour continuous infusion for 5 days. Vigorous hydration is necessary to prevent nephrotoxicity. In general, its clinical use is limited by the inconvenient method of administration, significant risk of nephrotoxicity, and cost.

Phosphate

Inorganic phosphates lower the serum calcium concentration by inhibiting bone resorption. They also promote the deposition of calcium salts in the bone and soft tissue. If given orally, phosphate reduces intestinal calcium absorption by forming a poorly soluble complex in the bowel lumen and also by decreasing the formation of active vitamin D through enzyme inhibition.[204]

When given IV, phosphate is very effective, but renal failure and extensive extraskeletal calcifications are a concern. For these reasons, IV phosphate is not the agent of choice for acute treatment of hypercalcemia.

Oral phosphate (1–3 g/day in divided doses) may be used for long-term maintenance therapy, with the optimal dose determined by serum calcium concentrations. Nausea, vomiting, and diarrhea are common problems, especially when the daily dose exceeds 2 g. Soft tissue calcification is also a concern, and hyperphosphatemia and hypocalcemia can occur if the dose is not titrated appropriately. Phosphate therapy should not be given to patients with hyperphosphatemia or renal failure because it can cause further deterioration of renal function. Accumulation of the potassium and sodium salts in phosphate preparations may also present a therapeutic problem in certain patients.

Corticosteroids

Several possible mechanisms exist that may explain the hypocalcemic effect of corticosteroids. Vitamin D_3–mediated intestinal calcium absorption may be impaired[205] and the action of osteoclast-activating factor, which mediates bone resorption in malignancy, may be inhibited. Corticosteroids may also have a direct cytolytic effect on tumor cells and inhibit the synthesis of prostaglandins (see the subsequent section, Prostaglandin Inhibitors). Prednisone in daily doses of 60–80 mg is given initially, with subsequent dosage reduction based on the calcemic response. Alternatively, hydrocortisone (5 mg/kg/day for 2–3 days) may be given. The hypocalcemic effect will not be apparent for at least 1 to 2 days. Patients with hematologic malignancies and lymphomas tend to have a better response than those with solid tumors. Corticosteroids are also effective in treating hypercalcemia associated with vitamin D intoxication,[205] sarcoidosis,[206] and other granulomatous conditions. They are not generally used for long-term therapy because of their potential for serious adverse reactions.

Prostaglandin Inhibitors

Because prostaglandins of the E series, especially PGE_2, may be responsible for hypercalcemia associated with some malignancies, NSAIDs may be useful for a select group of patients with hypercalcemia.[207] For example, indomethacin is effective in lowering the serum calcium concentration in patients with renal cell carcinoma but not in patients with other types of malignancy.[194] Indomethacin, 75 to 150 mg/day, can be tried in patients unresponsive to other therapy, especially when it is used as part of palliative treatment for cancer pain.

PHOSPHORUS

Homeostasis

Phosphorus is found primarily in bone (85%) and soft tissue (14%); less than 1% of the total body store resides in the ECF. Virtually, all of the "free" or active phosphorus exists as phosphates in the plasma. Most clinical laboratories, however, measure and express the concentrations of elemental phosphorus contained in the phosphate molecules. Phosphate of 1 mmol contains 1 mmol of phosphorus, but 1 mmol of phosphate is 3 times the weight of 1 mmol of phosphorus. Therefore, it is incorrect to equate a certain milligram weight of phosphorus as the same milligram weight of phosphate. Of the total plasma phosphorus, 70% exists as the organic form and 30% as the inorganic form. Organic phosphorus, primarily phospholipids and small amounts of esters, is bound to proteins. About 85% of inorganic phosphorus, or orthophosphate, is unbound or "free." The relative amounts of the two orthophosphate components, $H_2PO_4^-$ and HPO_4^{2-}, vary with pH. At pH 7.40, the ratio of the two species is 1:4, giving rise to a composite valence of 1.8 for the orthophosphate. Serum phosphate concentrations reported by clinical laboratories reflect only the inorganic portion of the total plasma phosphate. To avoid confusion related to the pH effect on valence, phosphate concentrations are reported as mg/dL or mmol/dL rather than mEq/volume.

The normal range of serum phosphate concentration in healthy adults is 2.5 to 4.5 mg/dL. The value is higher in children, possibly because of the increased amount of growth hormone and the reduced amount of gonadal hormones.[208] In postmenopausal women, the range is slightly higher; it is lower in older men. The serum phosphate concentration is also affected by dietary intake. Phosphate-rich foods can transiently increase the serum phosphate concentration. In contrast, glucose decreases the serum phosphate concentration because of the flux of sugar and phosphate into cells and because of the phosphorylation of glucose. Similarly, administration of insulin and epinephrine decreases the serum phosphate concentration because of their effects on glucose. The serum concentration of phosphate is reduced in alkalosis and increased in acidosis.[209]

A balanced diet contains 800 to 1,500 mg/day phosphorus. Both the organic and inorganic forms of phosphorus are present in food substances. Most of the phosphorus in milk is the organic form; the phosphorus in meat, vegetable, and other nondairy sources represents organic forms bound to proteins, lipids, and sugars, which usually are hydrolyzed before absorption.[210] In general, 60% to 65% of the phosphorus ingested is absorbed, mostly in the duodenum and jejunum through an energy-dependent, saturable, active process.[211] Phosphorus absorption is linearly related to the dietary intake when the intake is 4 to 30 mg/kg/day. The amount of phosphorus ingested probably is the most important factor in determining net absorption. Phosphorus absorption is also stimulated during periods of increased demand, such as active growth and pregnancy.[212] Increased intake of calcium and magnesium and concurrent use of aluminum hydroxide antacids may reduce phosphorus absorption owing to formation of a nonabsorbable complex.[213] In addition, absorption is also affected by vitamin D, PTH, and calcitonin.[208]

Renal phosphorus excretion depends on the dietary phosphorus intake. Normally, greater than 85% of the filtered phosphate load is reabsorbed; however, the fractional urinary excretion can vary from 0.2% to 20%. Renal phosphate excretion is also affected by acid–base balance, ECF volume, and calcium and glucose concentrations.[208] In addition, PTH, thyroid hormone, thyrocalcitonin, vitamin D, insulin, glucocorticoid, and glucagon can also alter renal phosphate excretion.[7]

Hypophosphatemia

ETIOLOGY

CASE 27-12

QUESTION 1: M.R., a 72-year-old woman, was admitted to the hospital with a 1-week history of increasing malaise, confusion, and decreased activity. M.R. has a history of HF, hypertension, type 2 diabetes, and peptic ulcer disease. She was receiving hydrochlorothiazide, aluminum–magnesium antacid, sucralfate, and insulin. She is febrile and in significant respiratory distress. ABG results at admission were pH, 7.5; PO_2, 42 mm Hg; and PCO_2,

---

20 mm Hg. Respiratory function continued to deteriorate, requiring intubation and mechanical ventilation. Serum electrolyte concentrations were as follows:

Na, 128 mEq/L
K, 3.6 mEq/L
Cl, 96 mEq/L
CO_2, 23 mEq/L
Glucose, 320 mg/dL
Phosphorus, 0.9 mg/dL

What may have contributed to the low serum phosphorus concentration in M.R.?

Hypophosphatemia can develop as the result of a phosphorus deficiency or secondary to a net flux of phosphorus out of the plasma compartment without a total body deficit. Moderate hypophosphatemia is defined as a serum phosphorus concentration of 1.0 to 2.5 mg/dL. A concentration of less than 1.0 mg/dL, as in M.R., is considered severe.[214] The extent of hypophosphatemia may not be assessed accurately by a single plasma phosphorus concentration determination because of diurnal variation.[215] Patients receiving large doses of mannitol may have pseudohypophosphatemia owing to the binding of mannitol with molybdate, which is used in the calorimetric assay for phosphorus.[216]

Hypophosphatemia is commonly caused by conditions that impair intestinal absorption, increase renal elimination, or shift phosphorus from the extracellular to the intracellular compartments. Hypophosphatemia secondary to low dietary phosphorus is exceedingly rare because phosphorus is ubiquitous.[208] In addition, renal phosphorus excretion is reduced and intestinal phosphorus absorption is increased to prevent a deficiency state.[217] Starvation in itself does not result in severe hypophosphatemia because the phosphorus content in plasma and muscles is often normal. Hypophosphatemia, however, can develop during refeeding with a high-calorie diet low in phosphorus. Therefore, hyperalimentation without phosphorus supplementation is likely to cause severe hypophosphatemia.[218]

Impaired phosphorus absorption secondary to malabsorptive conditions, prolonged nasogastric suction, and protracted vomiting can also result in hypophosphatemia. In M.R., the use of aluminum-containing and magnesium-containing antacids may further reduce phosphorus absorption. The antacids bind with endogenous and exogenous phosphorus in the GI tract and cause severe hypophosphatemia in patients with or without renal failure.[219] In addition, M.R. was taking sucralfate, which contains aluminum and can bind phosphorus in the GI tract.[220] Similarly, iron preparations can bind phosphorus.[221]

Hyperglycemia-induced osmotic diuresis and diuretic use may have increased the renal loss of phosphorus in M.R. Other conditions associated with renal phosphorus wasting include renal tubular acidosis, hyperparathyroidism, hypokalemia, hypomagnesemia, and extracellular volume expansion.[208] None of these situations, however, was evident in M.R. Shifting of phosphorus into the intracellular compartment by glucose or insulin and profound respiratory alkalosis may also have contributed to M.R.'s hypophosphatemic state.[222,223]

CASE 27-12, QUESTION 2: What other conditions are commonly associated with hypophosphatemia?

Diabetic ketoacidosis, chronic alcoholism, chronic obstructive airway disease, and extensive thermal burns are other conditions commonly associated with hypophosphatemia.[224,225] They are characterized by a combination of factors that result in phosphate loss and intracellular phosphate use. In patients with diabetic ketoacidosis, metabolic acidosis enhances the movement of phosphate from the intracellular compartment to plasma, whereas the concurrent osmotic diuresis secondary to hyperglycemia increases the renal elimination of extracellular phosphate.[226] The net result is a depletion of total body stores. Correction of the acidosis and administration of insulin then promotes the rapid uptake of phosphorus by tissues, and volume repletion dilutes the extracellular concentration. This sequence of events can ultimately lead to severe hypophosphatemia. The hypophosphatemia associated with chronic alcoholism and acute alcohol intoxication is also thought to be related to several factors, including reduced intestinal phosphorus absorption caused by vomiting, diarrhea, and antacid use; repeated acidosis that results in increased urinary phosphate excretion; and a shift of phosphorus into cells because of respiratory alkalosis. Renal phosphorus wasting can also result from hypomagnesemia or as a direct effect of alcohol.[226]

CLINICAL MANIFESTATIONS

CASE 27-12, QUESTION 3: What are the signs and symptoms associated with hypophosphatemia?

The clinical effects associated with chronic phosphorus depletion are often insidious and gradual in onset. In contrast, a rapid decline in plasma phosphorus concentrations results in sudden and serious organ dysfunction. Most of the effects can be attributed to impaired cellular energy stores and tissue hypoxia secondary to depletion of ATP or erythrocyte 2,3-diphosphoglycerate.[227] Severe hypophosphatemia can result in generalized muscle weakness, confusion, paresthesias, seizures, and coma. In addition, reduced cardiac contractility, hypotension, respiratory failure, and rhabdomyolysis have been observed with acute severe hypophosphatemia.[208] Chronic phosphorus depletion has been associated with decreased mentation; muscle weakness; osteomalacia; rickets; anorexia; dysphagia; cardiomyopathy; tachypnea; reduced sensitivity to insulin; and dysfunction of red blood cells, white blood cells, and platelets. Renal function is altered, as manifested by hypophosphaturia, hypercalciuria, hypermagnesuria, bicarbonaturia, and glycosuria. M.R.'s decreased mentation, weakness, and respiratory failure are consistent with severe hypophosphatemia.

TREATMENT

CASE 27-12, QUESTION 4: How can phosphate depletion be assessed? Outline a treatment regimen that would effectively and safely correct the phosphorus deficit in M.R. How should her therapy be monitored?

Phosphorus resides primarily in the intracellular space; the amount in the ECF is only a small percentage of the total body store. Because the patient's pH, blood glucose concentration, and insulin availability may affect phosphorus distribution, it is difficult to determine the magnitude of the phosphorus deficit based on the serum concentration alone. As discussed, a patient may have hypophosphatemia secondary to a rapid shift of phosphorus into the intracellular space without a total body deficit. The duration of the hypophosphatemia is often limited because it may be corrected by renal phosphorus conservation and oral intake of phosphorus-containing foods. Aside from serum phosphorus concentrations, urinary phosphorus excretion may be used to further assess the phosphorus deficit. Typically, renal phosphorus excretion is severely limited in patients with significant deficits. A phosphorus excretion of less than 100 mg/day (fractional phosphorus excretion <10%) confirms appropriate renal phosphorus conservation when the serum phosphorus

is less than 2 mg/dL. It also suggests a nonrenal etiology (e.g., impaired GI absorption) or some type of internal redistribution (e.g., respiratory alkalosis).[228]

Prophylactic supplementation should be used in situations that predictably increase the risk for developing hypophosphatemia. These include patients who are receiving total parenteral nutrition or large doses of antacids for an extended period, alcoholic patients, and those with diabetic ketoacidosis.

The specific treatment of hypophosphatemia depends on the presence of signs and symptoms, as well as the anticipated duration and severity of hypophosphatemia. In an asymptomatic patient with mild hypophosphatemia (1.5–2.5 mg/dL), who has no evidence of phosphorus depletion, phosphorus supplementation is generally not necessary because the condition is usually self-limited.[200] In other patients with mild and moderate hypophosphatemia, who have evidence of phosphorus deficit, oral supplementation is the safest and preferred mode of replacement. Skim or low-fat milk is a convenient source of phosphorus and calcium. Whole milk, because of its high fat content, can cause diarrhea if a large amount is consumed. Several oral phosphorus preparations can be used in patients who cannot tolerate milk products.

When hypophosphatemia is severe, as in M.R., or when the patient is vomiting or unable to take oral medication, parenteral phosphorus replacement is needed. Several empiric regimens have been evaluated. IV administration of 0.08 to 0.5 mmol/kg body weight of phosphorus over the course of 4 to 12 hours is safe and effective in restoring the serum phosphorus concentration.[228,229] More aggressive regimens, such as infusion over the course of 30 minutes to 2 hours, have also been suggested for critically ill and surgical patients.[230,231] Parenteral phosphorus replacement should be stopped once the serum phosphorus concentration reaches 2.0 mg/dL and also when oral supplementation is started. In general, no more than 32 mmol (1 g) of phosphorus should be administered IV in a 24-hour period. Regardless of the regimen used, serum phosphorus, calcium, and magnesium concentrations should be monitored closely because IV phosphorus administration can induce hyperphosphatemia quite rapidly, as well as hypocalcemia and hypomagnesemia. Monitoring of urine phosphorus concentration also helps determine the adequacy of therapy. Metastatic soft tissue calcification, hypotension, and, depending on the preparation used, potassium, sodium, or volume overload may occur. This could be significant in patients such as M.R. who have a history of HF and hypertension. Therefore, renal function and volume status should be monitored during therapy. Diarrhea, a common dose-related side effect of oral phosphorus replacement, can be minimized by diluting the supplement and slowly titrating the dose. Large doses can also result in metabolic acidosis.[228]

Phosphorus can be administered orally in doses of 30 to 60 mmol/day, usually given in two to four divided doses to minimize GI adverse events, using any commercially available oral supplement (e.g., Fleet or Neutra-Phos). Fleet Phospho-Soda (5 mL twice daily) delivers 40 mmol/day of phosphorus. Skim milk, the preferred agent for diluting the supplement, contains approximately 7 mmol of phosphorus/cup and provides calcium and potassium as well.

In M.R., oral supplementation was not feasible because she had intermittent diarrhea and vomiting. Potassium phosphate 15 mmol (providing 22 mEq of potassium) was therefore infused IV in 250 mL of 0.45% saline over the course of 12 hours. The regimen was repeated once until the serum phosphorus concentration reached 2 mg/dL. Oral supplementation with Fleet Phospho-Soda then was begun by adding one teaspoonful twice daily to her enteral tube feeding.

Hyperphosphatemia

Refer to the Mineral and Bone Disorders section in Chapter 28, Chronic Kidney Disease.

MAGNESIUM

Homeostasis

Magnesium is an intracellular cation found primarily in bone (65%) and muscle (20%). Only 2% of the total body store of 21 to 28 g (1,750–2,400 mEq) is located in the extracellular compartment. Serum magnesium concentrations, therefore, do not reflect the total magnesium body store accurately. In healthy adults, the serum magnesium concentration is 1.5 to 2.4 mEq/L, with approximately 20% of the serum magnesium bound to proteins.

Magnesium plays an important role in different metabolic processes, particularly in energy transfer, storage, and utilization. Cation deficiency can impair many ATP-mediated energy-dependent cellular processes as well as the action of phosphatases.[232] Magnesium is necessary for many enzymes involved in the metabolism of carbohydrate, fat, and protein, as well as RNA aggregation, DNA transcription, and degradation. The normal operation of many sodium, proton, and calcium pumps and the regulation of potassium and calcium channels are all dependent on the availability of intracellular magnesium.[233,234] In addition, adequate magnesium stores are needed to maintain normal neuronal control, neuromuscular transmission, and cardiovascular tone.

The average diet in North America contains about 20 to 30 mEq of magnesium.[235] The daily requirement is approximately 18 to 33 mEq for young persons and 15 to 28 mEq for women.[236] Normally, 30% to 40% of the elemental magnesium is absorbed, primarily in the jejunum and ileum. However, absorption may be increased to 80% in deficiency states and reduced to 25% during high magnesium intake. In patients with uremia, GI absorption of magnesium is decreased; however, absorption in the jejunum can be normalized by physiologic doses of 1α,25-dihydroxyvitamin D_3.[237] In addition, PTH also modulates magnesium absorption.[238]

Magnesium is eliminated primarily by the kidneys; only 1% to 2% of the endogenous magnesium is eliminated by the fecal route.[182] The magnitude of renal removal is determined by GFR and tubular reabsorption. Approximately 20% to 30% of the tubular reabsorption takes place in the proximal tubule, whereas Henle's loop, primarily the thick ascending limb, is responsible for up to 65% of the total reabsorption.[238] Only about 5% to 6% of the filtered magnesium is generally eliminated in the urine. The extent of magnesium reabsorption changes in parallel with sodium reabsorption, which is affected by the ECF volume. The renal threshold for urinary magnesium excretion is 1.3 to 1.7 mEq/L, which is similar to the normal plasma magnesium concentration. Slight changes in plasma magnesium concentration, therefore, may substantially alter the amount of magnesium excreted in the urine.[239]

Urinary magnesium reabsorption is affected by many factors, including sodium balance; ECF volume; serum concentrations of magnesium, calcium, and phosphate; and metabolic acidosis and alkalosis.[240] Concurrent use of loop and osmotic diuretics will also modulate the reabsorption.[241] Hormones, such as PTH, and possibly calcitonin, glucagon, and mineralocorticoids may affect the routine maintenance of magnesium balance as well.[242,243]

Hypomagnesemia

ETIOLOGY

CASE 27-13

QUESTION 1: R.J., a 61-year-old man, is admitted to the hospital because of trauma to his forehead after falling at home. He has a long history of conditions related to his alcohol abuse: liver disease, ascites, seizures, pancreatitis, and malabsorption. R.J. complained of abdominal pain, nausea, vomiting, and diarrhea for the past several days. At admission, R.J. was confused, apprehensive, and combative, and he had marked tremors. He also had delirium, as evidenced by hallucinations, screaming, and delusions, and he was having multiple tonic–clonic seizures. The medical record revealed that R.J. had been taking furosemide for the last 2 months. Pertinent laboratory test results obtained at admission were as follows:

K, 2.5 mEq/L
Magnesium, 0.8 mEq/L
Creatinine, 0.8 mg/dL

Phenytoin was administered for seizure control and R.J. was placed on nasogastric suction. Fluid restriction was instituted and furosemide therapy was continued to control his ascites. What are the circumstances that have contributed to R.J.'s hypomagnesemia?

Magnesium body stores are difficult to assess because magnesium is primarily an intracellular ion, and serum magnesium concentrations do not provide an accurate indication of the total body load. In fact, cellular magnesium depletion may be present with low, normal, or even high serum magnesium concentrations.[243,244] Conversely, hypomagnesemia may be seen without a net loss of body magnesium. Refeeding after starvation will result in increased trapping of magnesium by newly formed tissue, resulting in hypomagnesemia. Similarly, acute pancreatitis and parathyroidectomy can cause hypomagnesemia without a net loss of the cation.[245,246]

The prevalence of hypomagnesemia in ambulatory and hospitalized patients is approximately 6% to 12%.[247] The incidence increases to 42% in patients who are hypokalemic[248] and to 60% to 65% in those under intensive care.[249] Multiple risk factors and clinical conditions can contribute to the high rate of hypomagnesemia in critically ill patients.

Magnesium depletion and hypomagnesemia can develop owing to GI, renal, and endocrinologic causes. Depletion can occur in patients whose dietary magnesium intake is severely restricted[250] and in those who have protein calorie malnutrition.[251] Also at risk are patients who receive prolonged parenteral nutrition[252] and those who undergo prolonged nasogastric suction.[253] Hypomagnesemia may be present in patients who have increased magnesium requirements, such as pregnant women and infants.[254] Conditions associated with steatorrhea, such as nontropical sprue and short-bowel syndrome, can result in reduced GI magnesium absorption. Insoluble magnesium soaps may be formed in the GI tract because of the presence of unabsorbed fat.[255] Hypomagnesemia can also occur in patients with a bowel resection[256] and severe diarrhea.[257] A rare genetic disorder has also been reported in patients with defective GI magnesium absorption.[258] An impaired carrier-mediated magnesium transport system is believed to be responsible for the symptomatic deficiency, which requires high oral magnesium intake to overcome the defect.

Renal magnesium wasting can be caused by a primary defect or be secondary to systemic factors. A rare form of renal magnesium wasting is congenital.[259] Various drugs can induce hypomagnesemia through increased renal loss: cisplatin,[260] aminoglycosides,[261] cyclosporine,[262] and amphotericin B.[263] Use of loop and thiazide diuretics can also result in hypomagnesemia, which can be reversed with the concurrent use of amiloride or triamterene. Magnesium depletion can be associated with phosphate depletion,[264] calcium infusion,[265] and ketoacidosis.[266] Acute and chronic ingestion of alcohol will result in increased renal magnesium loss.[253,267] Various endocrinologic disorders, such as SIADH,[268] hyperthyroidism,[269] hyperaldosteronism,[244] and postparathyroidectomy,[271] are also associated with hypomagnesemia.

R.J. could be hypomagnesemic for many reasons. His long history of alcohol use, malnutrition, and malabsorption may all have contributed to his magnesium deficit. The vomiting and diarrhea that he experienced could have reduced GI magnesium absorption. Use of furosemide and nasogastric suction while in the hospital could also have exacerbated his magnesium depletion through renal and GI losses, respectively.

CLINICAL MANIFESTATIONS

CASE 27-13, QUESTION 2: What are the clinical manifestations of hypomagnesemia in R.J.?

Magnesium depletion can result in abnormal function of the neurologic, neuromuscular, and cardiovascular systems. Hypomagnesemia lowers the threshold for nerve stimulation, resulting in increased irritability. Typical findings include Chvostek and Trousseau signs, muscle fasciculation, tremors, muscle spasticity, generalized convulsions, and possibly tetany. The patient may experience weakness, anorexia, nausea, and vomiting, as seen in R.J. Hypokalemia, hypocalcemia, and alkalosis may be present as well. In patients who are moderately depleted, changes in the ECG include widening of the QRS complex and a peaking T wave.[272] In severe depletion, a prolonged PR interval and a diminished T wave may be seen. Ventricular arrhythmias have also been reported in some patients.[273]

TREATMENT

CASE 27-13, QUESTION 3: Outline a regimen to replenish the body stores of magnesium for R.J., and develop a monitoring plan to assess efficacy and potential adverse effects.

The specific regimen for magnesium replenishment depends on the clinical presentation of the patient. Symptomatic patients require more aggressive parenteral therapy, whereas oral replacement may suffice for asymptomatic hypomagnesemia. Patients with life-threatening symptoms, such as seizures and arrhythmias, need immediate magnesium infusion. Because serum magnesium concentrations do not reflect total body stores, symptoms are more important determinants of the urgency and aggressiveness of therapy.

The body stores of magnesium must be replenished slowly. Serum magnesium concentrations may return to the normal range within the first 24 hours, but total replenishment of body stores may take several days. Furthermore, approximately 50% of the administered IV dose of magnesium will be excreted in the urine.[273]

Because the threshold for urinary magnesium excretion is low, the abrupt increase in serum magnesium after an IV dose will result in increased urinary magnesium excretion despite a total body magnesium deficit. Conversely, in patients with renal insufficiency, decreased excretion of magnesium will place the patient at risk for hypermagnesemia. A reduced rate of magnesium administration and frequent monitoring of serum magnesium concentrations are therefore necessary in patients with renal dysfunction.

Oral replacement of magnesium is indicated for asymptomatic patients with mild depletion. Magnesium-containing antacids, milk of magnesia, and magnesium oxide are effective choices for replacement. Sustained-release preparations, such as Slow Mag

---

(magnesium chloride) or Mag-Tab SR (magnesium lactate), are preferred, however. With 5 to 7 mEq (2.5–3.5 mmol or 60–84 mg) of magnesium per tablet, six to eight tablets should be given daily in divided doses for severe magnesium depletion. For mild and asymptomatic disease, two to four tablets per day may be sufficient.[274] A diet high in magnesium (cereals, nuts, meat, fruits, fish, legumes, and vegetables) will also help replenish body stores and prevent depletion.[275]

For patients with symptomatic hypomagnesemia, such as R.J., parenteral magnesium replacement is indicated. The magnesium deficit in patients with chronic alcoholism is estimated to be 1 to 2 mEq/kg.[276] Because up to half of the IV magnesium dose will be excreted in the urine during replacement, approximately 2 to 4 mEq/kg will be needed to replenish R.J.'s body store.[277] Magnesium of 1 mEq/kg , as magnesium sulfate 10% solution, should be administered IV in the first 24 hours. Half of this amount is given in the first 3 hours, and the remaining half is infused over the course of the rest of the day. This dose may be repeated to keep the serum magnesium concentration greater than 1.0 mg/dL.[274] Later on, 0.5 mEq/kg of magnesium may be replenished daily for up to 4 additional days.[277,278] Magnesium can be given IM as 50% solution, but the injections are painful and potentially sclerosing, and multiple administrations are needed. Therefore, the IV route is the preferred mode of parenteral administration. For patients with symptomatic hypomagnesemia who are unstable, such as those experiencing seizures or life-threatening arrhythmias, 16 mEq of magnesium sulfate may be administered as a short IV infusion over the course of 2 minutes, followed by 16 mEq over the course of 20 minutes, then 16 to 24 mEq over the course of 2 to 4 hours.[278,279]

After IV magnesium administration, the patient should remain in a supine position to avoid hypotension. He should be monitored carefully for marked suppression of deep tendon reflexes (magnesium, 4–7 mEq/L); ECG, BP, and respiration changes; and high serum magnesium levels. Facial flushing, a sensation of warmth, and sweatiness may result from vasodilation secondary to a rapid magnesium infusion.[277] Particular caution is warranted in patients with renal impairment, in whom the rate of magnesium should be reduced. These patients should be monitored frequently to avoid toxicities related to hypermagnesemia. IV magnesium should also be administered cautiously in patients with severe atrioventricular heart block or bifascicular blocks because magnesium possesses pharmacologic properties similar to calcium channel blockers.[277,279]

In patients who exhibit hypomagnesemia secondary to a thiazide or loop diuretic, amiloride may be added to reduce renal magnesium loss by increasing reabsorption in the cortical collecting tubule.[274]

CASE 27-13, QUESTION 4: For the initial 2 days of hospitalization, R.J. received 3 mEq/kg of IV magnesium sulfate. However, his serum magnesium concentration remained less than 1.5 mEq/L. What might have contributed to the lack of favorable response to the magnesium therapy?

The total amount of magnesium administered to R.J. during the past 2 days was higher than the usual recommended rate (4–5 days) of magnesium replenishment, leading to renal excretion of a large portion of the dose.[280] Furthermore, the use of nasogastric suction and furosemide have increased the magnesium loss during the replacement period, and hypokalemia may have reduced the effectiveness of magnesium replacement. In a patient whose serum magnesium concentration does not increase after appropriate magnesium therapy, a 24-hour urine collection to assess magnesium renal excretion can be helpful. A low urinary magnesium concentration is consistent with magnesium depletion, whereas high urinary magnesium excretion in the presence of hypomagnesemia suggests renal magnesium wasting.

Hypermagnesemia

ETIOLOGY

CASE 27-14

QUESTION 1: J.O., a 63-year-old man with renal insufficiency, was admitted to the hospital because of increasing weakness during the past several days. J.O. began taking a magnesium–aluminum hydroxide antacid several times daily 2 weeks ago when he exhibited stomach upset. Physical examination reveals hypotension and depressed deep tendon reflexes. The ECG reveals prolonged PR and QRS intervals. The serum magnesium concentration is 6.5 mEq/dL. What is the most likely cause of hypermagnesemia in J.O.?

Because the kidney is the primary route of magnesium elimination, renal impairment is a virtual requisite for hypermagnesemia (see Chapter 28, Chronic Kidney Diseases). A common cause of hypermagnesemia is the use of magnesium-containing medications, such as antacids and laxatives, by patients with impaired renal function, including older adults. When a patient with renal failure, such as J.O., takes magnesium-containing medications, the serum magnesium concentration can increase substantially, resulting in toxicities. Hypermagnesemia may be seen when the creatinine clearance drops to less than 30 mL/minute; an inverse relationship is observed between the serum magnesium concentrations and the creatinine clearances.[281] Hypermagnesemia is also seen in patients with acute renal failure during the oliguric phase, but not the diuretic phase.[282] Other potential causes of hypermagnesemia include adrenal insufficiency,[232] hypothyroidism,[283] lithium,[283] magnesium citrate used as a cathartic for drug overdose,[284] and parenteral magnesium given for preeclampsia.[285]

CLINICAL MANIFESTATIONS

CASE 27-14, QUESTION 2: Describe the usual clinical presentation of a patient with hypermagnesemia.

An elevated magnesium serum concentration alters the normal function of the neurologic, neuromuscular, and cardiovascular systems. When the serum magnesium concentration is greater than 4 mEq/L, deep tendon reflexes are depressed; they are usually lost at greater than 6 mEq/L. Flaccid quadriplegia can develop when the concentration is greater than 8 to 10 mEq/L. Respiratory paralysis, hypotension, and difficulty in talking and swallowing may also be present. Changes in the ECG may include a prolonged PR interval and widening of the QRS complex. Complete heart block may be seen at concentrations of approximately 15 mEq/L. In mild hypermagnesemia, the patient may experience nausea and vomiting.

Drowsiness, lethargy, diaphoresis, and altered consciousness may be present at higher serum magnesium concentrations. J.O.'s increasing weakness, hypotension, depressed deep tendon reflexes, and ECG findings are consistent with hypermagnesemia.

TREATMENT

CASE 27-14, QUESTION 3: How should J.O.'s hypermagnesemia be treated?

If magnesium-containing medications are discontinued in patients with hypermagnesemia, the serum magnesium concentration will usually return to the normal range through renal elimination. When potentially life-threatening complications are present, as in J.O., 5 to 10 mEq of IV calcium should be administered to antagonize the respiratory and cardiac manifestations of magnesium.[285,286] The dose of the calcium can be repeated as necessary because its effect is short lived. In patients with good renal function without life-threatening complications, IV furosemide, plus 0.45% sodium chloride to replace lost urine volume, will enhance urinary magnesium excretion while preventing volume depletion. Hemodialysis or peritoneal dialysis is indicated for patients with significant renal function impairment and possibly for those with severe hypermagnesemia.

Chronic Kidney Disease

Darius L. Mason

CORE PRINCIPLES

		CHAPTER CASES
1	Chronic kidney disease (CKD) is progressive, irreversible kidney damage characterized by decreased estimated glomerular filtration rate (eGFR) or evidence of kidney damage for at least 3 months.	**Case 28-1 (Question 1)**
2	Classification of CKD staging should be determined on the basis of kidney function, defined by the Kidney Disease: Improving Global Outcomes (KDIGO). Each stage is associated with certain action plans.	**Case 28-1 (Question 1)**
3	Many equations exist for calculating creatinine clearance (CrCl) or eGFR. The Modification of Diet in Renal Disease (MDRD) equation is used to quantify GFR, to detect or stage the degree of CKD, and to follow progression. The Cockcroft–Gault (CG) equation is used to adjust the doses of medications that are eliminated by the kidneys.	**Equations 28-3–28-5**
4	Diabetes is the number one cause of CKD in the United States. Optimal control of blood glucose levels is essential to slow the progression of CKD and reduce morbidity and mortality.	**Case 28-1 (Questions 2–4)**
5	Fluid accumulation and electrolyte abnormalities secondary to CKD often complicate the treatment of hypertension and can have cardiotoxic effects.	**Case 28-1 (Questions 5–9)**
6	Metabolic acidosis presents in late stages of CKD from reduced hydrogen ion excretion and bicarbonate production. Metabolic acidosis can worsen bone disease and other metabolic processes.	**Case 28-1 (Question 8)**
7	Treating anemia of CKD is essential to reducing cardiovascular disease (CVD) complications. Management of anemia includes administration of iron supplementation and erythropoiesis-stimulating agents.	**Case 28-1 (Questions 10–12)**
8	CVD is the number one cause of morbidity and mortality in CKD. Cardioprotective measures should be addressed at all stages.	**Case 28-2 (Question 1)**
9	Hypertension is the second leading cause of CKD in the United States. Treating hypertension to target goals is necessary to slow the progression of CKD and reduce mortality.	**Case 28-2 (Question 2)**
10	Mineral and bone disorders (MBD) characterized by biochemical abnormalities, renal osteodystrophy, and vascular calcification become more common as CKD progresses. Biochemical abnormalities lead to	**Case 28-3 (Questions 1, 2)**

the development of vascular calcifications and increase the risk for cardiovascular mortality.	
⑪ Hyperphosphatemia is managed with dietary phosphorus restriction and phosphate-binding agents.	**Case 28-3 (Question 2)**
⑫ Activated forms of vitamin D (calcitriol, paricalcitol, and doxercalciferol) or a calcimimetic agent (cinacalcet) may be necessary to achieve proper biochemical balance and bone metabolism.	**Case 28-3 (Question 2)**
⑬ Glomerulonephropathies (GN) are a collection of glomerular diseases caused by a variety of immunologic mechanisms and the third leading cause of CKD. Patients with GN may present with nephrotic syndrome and require treatment with immunosuppressant therapy.	**Case 28-4 (Questions 1, 2),** **Case 28-5 (Questions 1, 2)**

INTRODUCTION

Chronic kidney disease (CKD) describes the continuum of kidney dysfunction from early to late-stage disease. Estimated glomerular filtration rates (eGFR) range from 90 mL/minute/1.73 m^2 in the early stages to less than 15 mL/minute/1.73 m^2 in the late stages of disease. The most advanced stage of CKD, known as end-stage renal disease (ESRD), occurs when chronic renal replacement therapy in the form of dialysis or kidney transplantation is necessary to sustain life.[1] Complications associated with CKD that increase the complexity of this condition include fluid and electrolyte abnormalities, anemia, cardiovascular disease (CVD), mineral and bone disorders (MND), and malnutrition. Optimal treatment of patients with CKD is best achieved using a multidisciplinary approach to address the concurrent medical problems and complex pharmacotherapeutic regimens. Alterations in drug disposition that occur with kidney impairment and the subsequent need for dosage adjustments are additional considerations when determining rational pharmacotherapy in this population.

Implementation of clinical practice guidelines leads to improved patient outcomes and reduced variability in patient care.[2] As a result many countries have developed evidence-based clinical practice guidelines for the treatment of kidney disease. In the United States, the National Kidney Foundation (NKF) established the Kidney Disease Outcomes Quality Initiative (K/DOQI) to provide evidence-based treatment guidelines for all stages of kidney disease and related conditions. However, because kidney disease is a worldwide public health issue and the problems faced by kidney disease around the world are universal, the Kidney Disease: Improving Global Outcomes (KDIGO) was established in 2003. The mission of KDIGO is to improve the care and outcomes of kidney disease patients worldwide by promoting coordination, collaboration, and integration of initiatives. KDIGO is managed by the NKF. Contact information for K/DOQI and KDIGO and corresponding web addresses for clinical practice guidelines can be found in Table 28-1.

Definition and Classification of CKD

CKD is characterized by a progressive deterioration in kidney function with time characterized by irreversible structural damage to existing nephrons. The KDIGO 2012 Clinical Practice Guideline for the Evaluation and Management of Chronic Kidney Disease defines CKD as abnormalities in kidney structure or damage (e.g., albuminuria) or function (e.g., decreased glomerular filtration rate or GFR) present for at least 3 months with implications for the patient's health (Table 28-2). CKD is classified by CGA categories (**c**ause of kidney disease, **G**FR, **a**lbuminuria) in the KDIGO guidelines. (Table 28-3 and Table 28-4).[1] The presence of the protein albumin in urine (defined as albuminuria) is an early and sensitive marker of kidney damage (Table 28-4). Unlike previous K/DOQI guidelines, KDIGO divides category three into two subcategories, 3a (GFR 45–59 mL/min/1.73 m^2) and 3b (GFR 30–44 mL/min/1.73 m^2), to better stratify patients based on the different outcomes and risks associated with these levels of GFR. Kidney damage is indicated by pathologic abnormalities of the kidneys or markers of kidney injury, including abnormalities in blood or urine tests and imaging studies.[1] Table 28-5 provides etiologic examples of CKD staging.

Table 28-2

Criteria for CKD[1]

Markers of Kidney Damage	Decreased GFR
■ Albuminuria (AER ≥30 mg/24 hours; ACR ≥30 mg/g [≥3 mg/mmol])	

■ Urine sediment abnormalities ■ Electrolyte and other abnormalities due to tubular disorders ■ Abnormalities detected by histology ■ Structural abnormalities detected by imaging ■ History of kidney transplantation	GFR<60 mL/minute/1.73 m^2

Must be at the defined GFR range or damage persisting for 3 months or greater.

AER, albumin excretion rate; ACR, albumin-to-creatinine ratio; CKD, chronic kidney disease; GFR, glomerular filtration rate.

Table 28-3

Staging of Chronic Kidney Disease Based on eGFR Category[1]

GFR Categories (mL/minute/1.73 m2)	Description	Range
G1	Normal or high	≥90
G2	Mildly decreased	60–89
G3a	Mildly to moderately decreased	45–59
G3b	Moderately to severely decreased	30–44
G4	Severely decreased	15–29
G5	Kidney failure	<15

CKD, chronic kidney disease; GFR, glomerular filtration rate.

Table 28-4

Albuminuria Categories: Description and Range[1]

	A1	A2	A3
Description	Normal to mildly increased	Moderately Increased	Severely Increased
Albumin-to-creatinine ratio (mg/g)	<30	30–300	>300
Albumin excretion rate (mg/24 h)	<30	30–300	>300

Table 28-5

Examples of CKD Staging[1]

Cause	GFR Category	Albuminuria Category	Criterion for CKD
Diabetic kidney disease	G5	A3	Decreased GFR, albuminuria
Idiopathic focal sclerosis	G2	A3	Albuminuria
Kidney transplant recipient	G2	A1	History of kidney

			transplantation
Polycystic kidney disease	G2	A1	Imaging abnormality
Vesicoureteral reflex	G1	A1	Imaging abnormality
Distal renal tubular acidosis	G1	A1	Electrolyte abnormalities
Hypertensive kidney disease	G4	A2	Decreased GFR and albuminuria
CKD presumed due to diabetes and hypertension	G4	A1	Decreased GFR
CKD presumed due to diabetes and hypertension	G2	A3	Albuminuria
CKD presumed due to diabetes and hypertension	G3a	A1	Decreased GFR
CKD cause unknown	G3a	A1	Decreased GFR

Patients above the thick horizontal line are likely to be encountered in nephrology practice. Patients below the thick horizontal line are likely to be encountered in primary care practice and in nephrology practice.

CGA, cause, GFR category and albuminuria category; CKD, chronic kidney disease; GFR, glomerular filtration rate.

A substantial decline in kidney function also leads to azotemia, the accumulation of nitrogenous wastes such as urea in the plasma, and an increased risk for developing complications of CKD. Uremic signs and symptoms from accumulation of nitrogenous wastes and other toxins manifest clinically as an elevated blood urea nitrogen (BUN) and lead to a myriad of complications affecting most major organ systems. Laboratory biochemical abnormalities include azotemia, hyperphosphatemia, hypocalcemia, hyperkalemia, metabolic acidosis, and worsening anemia. Clinical signs of CKD and its associated complications, including hypertension, uremic symptoms (e.g., nausea, anorexia), and bleeding, are observed as the disease advances to categories 3 through 5. Interventions to slow the progression of kidney disease are critical. Patients who reach an eGFR of less than 30 mL/minute/1.73 m^2 (category 4), in general, will ultimately progress to ESRD.

Epidemiology of Chronic Kidney Disease

INCIDENCE AND PREVALENCE

The United States Renal Data System (USRDS) is a national data system which collects, analyzes, and distributes information about all categories of CKD in the United States. Data describing CKD incidence and prevalence are made available annually by the USRDS and the USRDS provides data from approximately 2 years prior.[3] The 2014 USRDS report estimated CKD to affect 14% of the US population in 2012. Category 3 CKD reported the greatest increase in prevalence from 4.5% to 6.0%. The NKF's Kidney Early Evaluation Program (KEEP) screens high-risk individuals across the United States with high blood pressure (BP), diabetes, or a family history of kidney failure. Based on the high-risk participants from the KEEP screenings from 2000 to 2011, 24% of the participants had CKD.[4]

Based on the 2014 USRDS data from 2012, there were 114,813 new cases of ESRD; 102,277 of those cases started hemodialysis. This ESRD number includes peritoneal, hemodialysis, and transplant recipients. The rate of ESRD has declined each year since 2009. The 2012 adjusted incidence rate of 353/million/year was the lowest incidence rate since 1997. There were 449,342 patients receiving dialysis therapy (408,711 on hemodialysis and 40,631 on peritoneal dialysis) as of December 31, 2012. This was an increase in prevalence of 3.8% and 57.4% larger than in 2000. Prevalence was lowest in the New England and Northwest regions whereas it was highest in the Midwest regions. African Americans and Native Americans had a 3.3 and 1.85 times greater incidence rate of kidney failure, respectively, compared with white individuals. Hispanic patients had the highest ESRD incidence rate compared to the non-Hispanic population.[3]

In 2012, the majority of the increase in prevalence of ESRD occurred in patients aged 45 and over.[1] The age groups with the highest incidence of ESRD were those aged 65 to 74 years with 6,302 ESRD cases per million of the population. Those greater than age 75 had the greatest increase in cases at 50% since 2000. The African American population had the highest prevalence per million of the population that was 2-fold higher than Native Americans, 2.5-fold higher than Asians, and 4-fold higher than whites.[3]

CKD is a health priority identified as a disease prevention target for the Healthy People 2020 (HP2020) national health initiative; one of the specific CKD-related objectives is to reduce the number of cases of ESRD.[5] The HP2020 target rate of ESRD cases is 13.7% of the population. Currently, the adjusted prevalence from 1999 to 2004 is 15.2% of the population.[5] Additional objectives such as increasing awareness, improving cardiovascular care, and reduction of mortality in CKD patients can be found at the HealthyPeople.gov website.

ETIOLOGY

In CKD, the progressive loss or damage to functioning nephrons as a function of time is the result of a primary disorder or disease of the kidney, a secondary complication of certain systemic diseases (e.g., diabetes mellitus or hypertension), or an acute injury to the kidney that results in irreversible kidney damage. In 2012, the leading causes of ESRD in newly diagnosed American patients were diabetes mellitus (44%), hypertension (28%), and chronic glomerulonephritis (GN; 7%).[3] The remaining cases of ESRD can be attributed to a variety of other pathologies; examples include polycystic kidney disease, congenital malformations of the kidneys, nephrolithiasis, interstitial nephritis, renal artery stenosis, renal carcinoma, and human immunodeficiency virus–associated nephropathy.

RISK FACTORS

A variety of risk factors associated with development, initiation, and progression of

CKD have been identified. Initiation factors are medical conditions that directly cause kidney damage. Risk factors for the progression of CKD exacerbate kidney damage and are related to an accelerated decline in kidney function with time. The majority of susceptibility factors are not modifiable, but may identify people who are at high risk for developing CKD. In contrast, pharmacotherapy and lifestyle interventions have been shown to modify CKD-related initiation and progression factors (see Prevention and Diabetic Nephropathy section). A summary of risk factors associated with CKD can be found in Table 28-6.

Table 28-6

Risk Factors for Chronic Kidney Disease

Susceptibility	Initiation	Progression
Advanced age Reduced kidney mass Low birth weight Racial/ethnic minority Family history Low income or education Systemic inflammation Dyslipidemia	Diabetes mellitus Hypertension Glomerulonephritis Drug induced or toxicity Smoking Obesity	Glycemia Hypertension Proteinuria Smoking Obesity

KDOQI. KDOQI clinical practice guidelines for chronic kidney disease: evaluation, classification, and stratification. Am J Kidney Dis. 2002;39(2, Suppl 1):S73.

MORBIDITY AND MORTALITY

Rates of hospitalizations and mortality are much greater in those with kidney disease compared with the non-CKD population. Not surprisingly, mortality rates increase with progressing stages of CKD, patient health complexity, and age. The mortality rate of non-dialysis patients with CKD was 36% higher compared with those without CKD, and the adjusted rates of all-cause mortality were 6 to 8 times higher for dialysis patients compared with the general population.[3]

Advances in dialysis and transplantation have improved patient care, and as a result, mortality rates continue to decline. From 2003 to 2012, the mortality rate fell by 25%, whereas from 1993 to 2002, there was only a 9% reduction in mortality.[3] Cardiovascular-related events, particularly cardiac arrest and myocardial infarction, remain the leading causes of hospitalizations and death in both the non–dialysis CKD and ESRD populations. This is not surprising given the high prevalence of coexisting cardiac disorders in patients with kidney disease and the elevated risk for mortality associated with these conditions. However, since 1999, the overall rate of cardiovascular mortality in the ESRD population has continued to decline. After

CVD, infection (predominantly septicemia) is a substantial contributor to overall morbidity and mortality in patients with ESRD.[3]

The mortality rates during the first year of hemodialysis are the highest. However, reductions in the first year of hemodialysis have decreased by 19%, 30%, and 56% for all-cause, cardiovascular, and infection death as compared to 2001, respectively. Although improvements in mortality are acknowledged, only 54% and 65% of hemodialysis and peritoneal dialysis patients survive beyond 3 years after ESRD onset.[3]

Medication Use

Data regarding medication use in the kidney disease population reveal non–dialysis CKD patients are prescribed an average of 6 to 8 medications and HD patients are prescribed approximately 12 medications (10 home medications and 2 in-center medications).[5,6] These patterns of medication use are reflective of the higher prevalence of complications and comorbidities in the latter stages of CKD, which require additional drug therapies. The extent of medication use and the complexity of prescribed drug regimens contribute to nonadherence and medication-related problems (MRPs) in the ESRD population.[7]

To manage MRPs, some dialysis units use a clinical pharmacist as part of the multidisciplinary health care team to provide pharmaceutical care to ESRD patients. Services provided by a clinical pharmacist have been shown to be cost-effective and associated with maintenance of health-related quality of life.[8,9] Additionally, a randomized study of 104 ESRD patients investigated the impact of pharmaceutical care (individualized drug therapy reviews conducted by a clinical pharmacist) to standard care (brief drug therapy reviews conducted by a nurse) on drug use, drug costs, hospitalization rates, and MRPs. After a 2-year follow-up, patients who received pharmaceutical care were taking fewer medications and had fewer all-cause hospitalizations compared with those receiving standard care.[10]

Economics

The cost of treating both non–dialysis CKD patients and ESRD patients is substantial. In 2012, the overall per person per year cost of medical treatment for Medicare non–dialysis CKD patients was more than $20,162 and the cost of medical care for those with stages 4 to 5 CKD was 1.4 times higher than those with CKD stages 1 to 2.[3] Furthermore, the majority of the costs of medical care provided to those with ESRD are paid by the federal government. In 2012, the cost for ESRD was $28.6 billion dollars, corresponding to 5.6% of the Medicare budget.[3] This amount reflects a consistent increase from prior years. The increase is most likely associated with the higher prevalence of ESRD, changes in the standard of care, reimbursement structure, and types of patients being treated (e.g., diabetic patients versus nondiabetic patients).

The continually growing costs of ESRD care require careful attention, given the implementation of the Centers for Medicare and Medicaid Services' bundled payment system that changed how Medicare pays for dialysis services. Under the bundled system, Medicare provides a single payment to ESRD facilities to cover all dialysis-related services for each dialysis treatment.[10] In the prior reimbursement system, Medicare paid a composite rate to dialysis units to cover the costs of an individual's dialysis treatment, certain routine medications (e.g., heparin), laboratory tests, and supplies. In addition to the composite rate, Medicare was billed separately for other related dialysis services and billable items (e.g., erythropoietin [EPO]-stimulating agents).[8] The bundled payment system is likely to reduce the government reimbursement for dialysis services, but may increase barriers to care for some ESRD patients.[10]

Pathophysiology

Progression of kidney disease to ESRD generally occurs over the course of months to years and is assessed by the rate of GFR decline. Each kidney contains approximately 1 million nephrons (the functional units of the kidney), and every nephron maintains its own single-nephron GFR. In the face of nephron loss, the remaining functional nephrons maintain renal function by increasing their single-nephron GFR via compensatory glomerular hemodynamic changes.[9] With time, this compensatory increase in single-nephron GFRs eventually leads to hypertrophy and an irreversible loss of nephron function from sustained increases in glomerular pressure. Furthermore, glomerulosclerosis (glomerular arteriolar damage) develops from prolonged elevation of glomerular capillary pressure and increased glomerular plasma flow, resulting in a continuous cycle of nephron destruction. Regardless of the cause, a predictable and continuous decrease in kidney function occurs in patients when the eGFR drops below a critical value, approximately one-half of normal.[11] Usually, the rate of decline in kidney function remains fairly constant for an individual, but can vary substantially among patients and disease states. A rapid rate of decline in kidney function has been associated with black race, proteinuria, male sex, older age, and smoking.[12–14] Rapid progression of kidney disease is defined as persistent decline in GFR >5 mL/minute/1.73 m^2/year.[1] Although early changes in kidney function can be detected through routine laboratory monitoring (e.g., serum creatinine [SCr]), most patients do not develop signs and symptoms of uremia until they have reached the more severe stages of the disease (i.e., CKD categories 4, 5, and/or ESRD).

As the leading causes of ESRD in the United States, diabetes mellitus, hypertension, and glomerular diseases have been the focus of research to identify their associated mechanisms of kidney damage. In the case of diabetes mellitus, excess filtration of glucose, excessive glucose contact with the glomerular and tubular cells leads to increased cellular osmotic pressure and thickening of the capillary basement membrane and other anatomic changes. Systemic hypertension is a potent stimulus for the development and progression of kidney disease caused by the association with increased single-nephron GFRs.[9,14] Hypertension, whether the primary cause of kidney disease or a coexisting disease in the presence of other etiologies, can promote kidney damage through transmission of elevated systemic pressure to glomeruli. The result is glomerular capillary hyperperfusion and hypertension leading to progressive kidney damage as nephron destruction continues. Glomerular ischemia induced by damage to the preglomerular arteries and arterioles also occurs. People with coexistent diabetes mellitus and hypertension increase the risk of developing ESRD by fivefold to sixfold compared with those with hypertension alone.[11] Most glomerular diseases are mediated by immune mechanisms. The deposition and formation of immune complexes in the glomerulus cause injury, resulting in increased glomerular permeability to macromolecules (e.g., proteins).[15]

Proteinuria, one of the initial diagnostic signs of kidney disease, also contributes to the progressive decline in kidney function. A faster rate of progression is associated with higher protein excretion.[16] Immunologic and hemodynamic mechanisms have been identified to explain the glomerular injury. Increases in kidney plasma flow are associated with proteinuria and high protein intake. Inflammatory cytokines may be responsible for fibrosis and kidney scarring, ultimately resulting in loss of nephron function.

Dyslipidemias are common in patients with CKD and often observed concurrently with proteinuria. Increased low-density lipoprotein (LDL) cholesterol, total cholesterol, and apolipoprotein B, as well as decreased high-density lipoprotein (HDL) cholesterol, have been observed in patients with progressive kidney disease.[15] Hypercholesterolemia has been associated with loss of kidney function in patients with and without diabetes.[17,18] Accumulation of apolipoproteins in glomerular mesangial cells contributes to cytokine production and infiltration of macrophages and has been implicated in the progression of CKD, primarily in the presence of previous kidney disease or other risk factors such as hypertension.[17] LDL is thought to promote glomerular damage by initiating a series of cellular events in mesangial cells and through oxidation to a more cytotoxic derivative once within these cells. Although serum total cholesterol, triglycerides, and apolipoprotein B all correlate with the rate of decline in eGFR, it is not clear that they directly increase the rate of progression of kidney disease, particularly when present with concomitant conditions that also cause kidney damage. Some evidence, however, suggests that treatment of hypercholesterolemia with statin therapy in patients with CKD may reduce proteinuria and progression of CKD.[19]

Drug-Induced Causes of Chronic Kidney Disease

ANALGESIC NEPHROPATHY

Analgesic nephropathy results from habitual ingestion of analgesics for many years. Particularly, agents containing at least two antipyretic analgesics and usually caffeine or codeine are commonly associated with the development of analgesic nephropathy. It is a tubulointerstitial kidney disease characterized by renal papillary necrosis as a primary lesion and chronic interstitial nephritis as a secondary lesion.[20] Analgesic nephropathy is a slowly progressive disease, and the clinical signs and symptoms are similar to the nonspecific presentation of CKD attributable to any other etiology. Phenacetin, an acetaminophen prodrug, was the first agent to be identified as causing this syndrome.

Currently in the United States, most cases are caused by long-term use or misuse of compound analgesics containing acetaminophen and aspirin along with caffeine or codeine. Similar findings in terms of the effect on kidney function have also been observed with chronic nonsteroidal antiinflammatory drug (NSAID) therapy.[21] The uses of acetaminophen, aspirin, and NSAIDs have been associated with the progression of kidney disease in CKD patients in a dose-dependent manner.[22] The cumulative amount (at least 1–2 kg of acetaminophen), rather than the duration of analgesic intake, is a primary risk factor for developing chronic analgesic nephropathy.[23,24] Thus, analgesics should be used with caution in the CKD population, and chronic analgesic therapy should be discouraged. KDIGO guidelines recommend discontinuation of NSAIDs in people with a GFR <60 mL/minute/1.73 m^2.[1]

Analgesic nephropathy is more prevalent in female patients, with a female to male ratio of 5:1 to 7:1. The peak incidence occurs between the fourth and fifth decades of life.[20,24] Patients usually have a history or complaint of chronic pain syndromes. Often, patients who develop analgesic nephropathy are dependent on analgesic therapy and may exhibit psychiatric manifestations indicative of an addictive behavior. At presentation, patients may have a reduced GFR and findings consistent with CKD, such as elevated SCr, BUN, and proteinuria. However, during acute necrosis, patients may experience flank pain, pyuria, and hematuria. As necrosis progresses, cellular debris may cause ureteral obstruction. Kidney dysfunction is characterized as a salt-wasting nephropathy, with a substantial reduction in urine-concentrating and urine-acidifying capabilities. The exact mechanism for kidney damage is uncertain, but it is thought that because acetaminophen accumulates in the renal medulla, its oxidative metabolite produced by the medullary cytochrome P-450 enzyme system may bind to macromolecules, causing cellular necrosis. Although the reduced form of glutathione in the medulla can prevent this process, agents that reduce medullary glutathione content (e.g., aspirin) may promote kidney damage. This mechanism may explain a lack of analgesic nephropathy associated with acetaminophen alone. NSAIDs, which attenuate prostaglandin-mediated vasodilatation, may induce an ischemic state within the renal medulla, leading to papillary necrosis.[21]

Data on the chronic kidney effects of selective cyclooxygenase-2 (COX-2) inhibitors are limited compared to traditional NSAIDs. A meta-analysis of 114 randomized, double blind clinical trials evaluated the adverse kidney events of COX-2 inhibitors. The authors reported that, of the six agents evaluated, only rofecoxib was associated with adverse kidney effects, defined as significant changes in urea or creatinine levels, clinically diagnosed kidney disease, or kidney failure. In contrast, celecoxib was associated with a lower risk of kidney dysfunction.[21] A cohort study of 19,163 newly diagnosed CKD patients examined the association between analgesic use and the risk of progression to ESRD. Among the COX-2 inhibitors, only rofecoxib use was significantly associated with an increased risk of progression to ESRD.[22]

The long-term management of analgesic nephropathy is generally supportive and primarily involves discontinuation of the offending agent and subsequent abstinence from the use of NSAIDs and combination analgesics. If patients develop CKD or ESRD, treatment of kidney disease-related comorbidities should be treated in the same manner as those with kidney disease owing to any other cause. For patients requiring analgesics, aspirin taken alone may be a reasonable alternative. Acetaminophen as a single agent may be safe, although habitual use can contribute to progression of kidney disease as well as to liver toxicity.[23,24] CKD patients requiring chronic analgesic therapy should use the lowest dose to control pain, avoid combination products when possible, and maintain adequate hydration.

LITHIUM NEPHROPATHY

Lithium use has been associated with alterations in kidney function secondary to acute functional and histologic changes and has been associated with the development of chronic pathologic changes to the kidneys (e.g., chronic interstitial nephritis). The role of lithium as a causative agent in the development of CKD has been suggested in a variety of epidemiologic, clinical, and histopathologic studies.[25] The concentrating ability within the kidney and GFR have been shown to decline with long-term lithium use.[26] Lithium-induced chronic renal disease has a slow progression (average latency between onset of lithium use and ESRD is 20 years) in which the rate of progression is related to the duration of lithium therapy.

Patients with lithium nephropathy are generally asymptomatic. They typically present with an insidious decline in renal function over the course of many years, and proteinuria is usually absent or minimal.[25] Women are generally at greater risk than men.[26] In patients taking chronic lithium therapy, close monitoring of serum lithium concentrations is advised, and regular measurements of SCr should be obtained to detect changes in kidney function. Higher lithium concentrations are associated with increased renal risk.[26] Current clinical practice guidelines recommend monitoring SCr every 2 to 3 months during the first 6 months of chronic lithium therapy, followed by yearly measurements thereafter.[25] If patients develop CKD or ESRD, management of kidney disease–related comorbidities should be treated in the same manner as those with kidney disease owing to any other cause. The decision to discontinue lithium and to initiate another mood stabilizer should be a mutual decision made by the psychiatrist, the nephrologist, and the patient. The diuretic amiloride has been suggested to reduce lithium-induced renal adverse effects.[25]

Clinical Assessment

QUANTIFYING GLOMERULAR FILTRATION RATE

One of the most widely used clinical measures to determine baseline kidney function and monitor progression of kidney disease with time is eGFR. The ideal marker of eGFR should be a nontoxic substance that is freely filtered at the glomerulus and not secreted, reabsorbed, or metabolized by the kidney. Inulin and exogenous radioactive markers, such as ^{125}I-iothalamate or ^{51}CrEDTA, have been used to assess GFR because they meet these criteria; however, they are not readily available to clinicians, require intravenous (IV) administration, and are costly.

Creatinine is an endogenous substance that is produced at a relatively constant rate by nonenzymatic hydrolysis of muscle stores of the amino acid derivatives creatine and phosphocreatine. Under steady-state conditions, the urinary excretion of creatinine equals the creatinine production rate, and the SCr concentration remains relatively stable. Creatinine is excreted primarily by glomerular filtration—thus, creatinine clearance (CrCl) has been used as a reasonable surrogate for eGFR. There are limitations to consider when using methods to assess eGFR that incorporate creatinine. Creatinine is eliminated not only through glomerular filtration but also by tubular secretion. Consequently, the CrCl overestimates the true GFR by 10% to 20%. As nephron function declines, tubular secretion of creatinine contributes more substantially to overall elimination such that CrCl overestimates true GFR. Extrarenal elimination of creatinine in the gastrointestinal (GI) tract may also lead to overestimation of actual GFR.[27] As a result of these processes, disease progression may be underestimated. Commonly used drugs also need to be taken into consideration when interpreting SCr values. For example, trimethoprim can inhibit the secretion of creatinine, and increase SCr and decrease CrCl without affecting GFR. On the other hand, cimetidine has been administered to block tubular secretion of creatinine before measurement of CrCl for a more accurate assessment of GFR.[16]

SCr alone is used clinically as an index of kidney function; however, multiple limitations to this practice exist. In the initial stages of kidney disease, SCr may remain within the normal range. Consequently, SCr may be relatively insensitive in detecting early kidney disease and is not accurate for estimating the progression of the disease. Because generation of creatinine is proportional to total muscle mass, it is affected by diet (notably by the ingestion of meats), age, and sex. Generally, muscle mass declines with age and is lower in women. Thus, a SCr that is in the upper limit of normal (e.g., 1.2 mg/dL) for a young male athlete is likely to be associated with a high CrCl, whereas the same SCr in a 70-year-old woman could indicate compromised kidney function.

Use of SCr to assess kidney function in patients with liver disease may also lead to overestimation of GFR.[28] This may be attributed to decreased production of creatine (the precvursor of creatinine) by the liver or increased tubular secretion of creatinine by the kidney. Also, substantial variation is seen in the calibration of SCr among laboratories that can result in differences in measured SCr. The National Kidney Disease Education Program Laboratory Working Group initiated the creatinine standardization program to improve and normalize SCr results, reduce interlaboratory variability, and enable more accurate eGFR determinations.[29] Although SCr can provide a rough estimate of kidney function, other markers of early kidney damage, such as proteinuria, should also be evaluated in patients at risk for kidney disease.

Several equations have been developed to calculate CrCl or eGFR.

The Cockcroft–Gault (CG) equation (Eq. 28-1). has been the most commonly used method to estimate kidney function for drug dosing, which provides an estimate CrCl in patients with stable renal function[27,30]:

$$\mathrm{CrCl} = \frac{(140 - \mathrm{Age})(\mathrm{IBW})}{(72)} \qquad \text{(Eq. 28-1)}$$

where age is in years, IBW is ideal body weight in kg (male IBW = 50 + [2.3 × height >60 inches]; female IBW = 45 + [2.3 × height >60 inches]), and SCr is the serum creatinine concentration (mg/dL). For women, the CG equation is multiplied by 0.85 to account for decreased muscle mass.

The CG equation should not be used to estimate GFR in patients with rapidly changing SCr concentrations because it was derived from normal, healthy subjects with stable kidney function. The CG equation is also inaccurate in populations that have low muscle mass—such as elderly, obese, or cachectic patients.

The Schwartz equation[31] is used in children (Eq. 28-2):

$$\text{Cr Cl (mL/minute)} = \frac{(k \times \text{length [in cm]})}{\text{SCr}} \qquad \text{(Eq. 28-2)}$$

where k is dependent on age (infant [1–52 weeks] k = 0.45; child [1–13 years] k = 55; adolescent male k = 0.7; and adolescent female k = 0.55), and SCr is the serum creatinine concentration (mg/dL).

The most commonly used method for kidney function assessment is the prediction equation developed using data from the Modification of Diet in Renal Disease (MDRD) study, a multicenter trial that evaluated the effects of dietary protein restriction and BP control on progression of kidney disease. This equation, referred to as the MDRD equation, was derived using GFR measured directly by urinary clearance of a radiolabeled marker (^{125}I-iothalamate) as opposed to creatinine, and included a relatively large and diverse population (>500 white and black individuals with varying degrees of kidney disease) for derivation and validation of the equation. The MDRD equation[32] is as follows (Eq. 28-3):

$$\begin{aligned}&\text{Estimated GFR}\\ &(\text{mL/minute/1.73 m}^2) = 170 \times (\text{SCr})^{-0.999}\\ &\qquad \times (\text{Age})^{-0.176} \times (\text{BUN})^{-0.170} \qquad \text{(Eq. 28-3)}\\ &\qquad \times (\text{Alb})^{+0.318} \times (0.762 \text{ if female})\\ &\qquad \times (1.18 \text{ if black})\end{aligned}$$

where SCr is the serum creatinine concentration (mg/dL), age is in years, BUN is the blood urea nitrogen concentration (mg/dL), and Alb is the serum albumin concentration (g/dL).

An abbreviated version was developed and is referred to as the four-variable MDRD equation (Eq. 28-4)[1]:

$$\begin{aligned}&\text{Estimated GFR}\\ &(\text{mL/minute/1.73 m}^2) = 186 \times (\text{SCr})^{-1.154} \qquad \text{(Eq. 28-4)}\\ &\qquad \times (\text{Age})^{-0.203} \times (0.742 \text{ if female})\\ &\qquad \times (1.21 \text{ if black})\end{aligned}$$

where SCr is the serum creatinine concentration (mg/dL) and age is in years. Subsequently, this equation was reexpressed in 2005 for use with a standardized SCr assay enabling consistent results across clinical laboratories to improve accuracy in eGFR determinations (Eq. 28-5).[27]:

$$\text{Estimated GFR} \; (\text{mL/minute/1.73 m}^2) = 175 \times (\text{standardized SCr})^{-1.154} \times (\text{Age})^{-0.203} \times (0.742 \text{ if female}) \times (1.21 \text{ if black}) \qquad \text{(Eq. 28-5)}$$

where SCr is the serum creatinine concentration (mg/dL) and age is in years. The National Kidney Disease Education Program recommends this equation for laboratories using a creatinine method that has its calibration standardized by isotope dilution mass spectrometry.

The MDRD equation was found to be biased and imprecise at higher GFRs with the potential of misidentifying patients with high GFR as having poor kidney function.[1,33] The Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) research group established by the National Institute of Diabetes and Digestive and Kidney Diseases pooled studies of different populations to develop and validate a new estimating equation for GFR that is more complex, but uses the same variables as the MDRD equation.[1,34] The CKD-EPI equation was found to be more accurate than the MDRD equation, especially at high GFRs and across a wider range of body mass index.

An important point is that the results from the MDRD and CG equations are not interchangeable. That is, the MDRD equations are used to quantify GFR, to detect or stage the degree of CKD, and to follow progression. The CG equation is most commonly used to evaluate the appropriate doses of drugs that are eliminated by the kidney[27] (see Chapter 31, Dosing of Drugs in Renal Failure).

Cystatin C is another endogenous marker of kidney function that is freely filtered at the glomerulus. Subsequently, it is reabsorbed and catabolized by proximal tubular epithelial cells. Unlike SCr, cystatin C is not influenced by gender, age, body mass, and nutritional status. Several equations based on serum cystatin C levels either alone or in combination with SCr and other demographic variables have been developed.[1,35] The KDIGO guidelines suggest the use of a Cystatin C–based equation test for confirmatory testing of GFR when eGFR based on SCr is less accurate.[1]

PROTEINURIA

Normally, proteins are not filtered at the glomerulus because of their relatively large molecular size. Thus, only trace amounts of protein are present in the urine in patients without kidney disease. However, with glomerular damage, proteinuria is commonly observed and may precede elevations in SCr. The amount of protein present in the urine has been shown to be a predictor of kidney disease progression. As a result, protein excretion should be monitored in patients at risk for kidney disease as well as those with existing kidney disease at routine checkups.

Proteinuria is defined as a total protein excretion rate >200 mcg/minute or >300 mg/24 hour (referred to as albuminuria; if albumin is the only protein measured). Measurement of total protein includes quantification of albumin plus other proteins, such as low molecular weight globulins and apoproteins. Assessment of albuminuria is a better indicator of early kidney disease because it is primarily indicative of glomerular damage as opposed to total protein, which is not specific for glomerular damage. Other tests, including urinalysis (UA), radiographic procedures, and biopsy, may also be valuable in further assessing kidney function.

Determination of albuminuria can be done using timed urine samples (Table 28-4). Typically, a 24-hour collection period termed albumin excretion rate (AER) is used, although a timed sample collected overnight may be more reliable because albumin excretion can vary throughout the day and with postural changes (i.e., orthostatic proteinuria). Untimed or "spot" urine samples for measurement of albumin-to-creatinine ratios (ACR) are more convenient. As opposed to measuring protein or albumin in a timed collection, this method corrects for variations in hydration status and may be more accurate because protein excretion is normalized to glomerular filtration. The albumin and creatinine concentrations in the urine are measured from a spot urine sample, preferably from first morning urine sample, because it correlates best with 24-hour albumin excretion. If a first morning urine

---

sample is not available, a random sample is acceptable. Factors associated with albuminuria, such as ingestion of a high-protein meal and vigorous exercise, must be considered when evaluating urinary albumin. Measuring urinary protein after exercise will result in a falsely elevated urine protein level as a consequence of an increase in the membrane permeability of the glomeruli to protein and a saturation of the tubular reabsorption process of filtered protein. To minimize this risk, it is recommended to wait approximately 4 hours after exercise to test for proteinuria.[36] Screening for albuminuria can also be done using urine dipstick testing of a spot urine sample. Reagent strips are available from several commercial vendors and differ with regard to the specified testing procedure and the sensitivity and specificity for detecting albuminuria. Patients with a positive dipstick screening test should have a subsequent quantitative assessment of the ACR to confirm proteinuria. The KDIGO Guidelines for Evaluation and Management of CKD provide criteria for albuminuria categories (Table 28-4).[1]

COMPLICATIONS OF CHRONIC KIDNEY DISEASE

Complications specific to CKD begin to develop as kidney disease progresses, most often when patients reach CKD 3 (eGFR <60 mL/minute/1.73 m^2). These complications include fluid and electrolyte abnormalities, metabolic acidosis, anemia, MND, cardiovascular complications, and poor nutritional status. Often, these complications go unrecognized or are inadequately managed during the earlier stages of CKD, leading to poor outcomes by the time a patient is in need of dialysis therapy. Hypoalbuminemia and anemia were identified in more than 50% of a population of patients new to dialysis therapy, and these findings were associated with a decreased quality of life.[37] Late referral to a nephrologist to manage CKD and its associated complications has also been associated with increased mortality in the ESRD population.[37] The KDIGO guidelines recommend referral of patients to a nephrologist in any of the following circumstances: AKI or an abrupt fall in GFR, a GFR <30 mL/minute/1.73 m^2, persistent albuminuria (ACR ≥ 300 mg/g), progression of CKD, unexplained persistence of red blood cell (RBC) casts and >20 RBCs per high-power field in UA, persistent abnormalities in potassium, extensive nephrolithiasis, hereditary kidney disease, CKD with resistant hypertension on four or more antihypertensive agents, and in all patients in whom the risk of progression to CKD 5D (CKD category 5 receiving dialysis) in the next year is estimated at 10% to 20% or greater.[1] These and similar reports underscore the need for early and aggressive therapy to manage complications of CKD. Complications of CKD will be presented in more detail throughout this chapter, and complications associated with dialysis therapy are discussed in Chapter 30, Renal Dialysis.

Prevention

Appropriate management of CKD includes measures to slow progression of the disease and regular evaluation of kidney function to assess changes in disease severity and to monitor therapy. This includes aggressive strategies to manage the disorders that cause kidney disease or are known to accelerate the disease process, such as diabetes mellitus, hypertension, high protein intake, and dyslipidemias (see Chapter 8, Dyslipidemias, Atherosclerosis, and Coronary Heart Disease; Chapter 9, Essential Hypertension; and Chapter 53, Diabetes Mellitus).

DIETARY PROTEIN RESTRICTION

Proteinuria is a significant predictor of ESRD in patients with CKD.[38,39] Increases in protein ingestion are associated with a rise in eGFR, possibly as a result of structural changes of the glomerulus and changes in renal plasma flow with an increased protein load.[40] Evidence such as this has led to the investigation of methods to reduce the degree of proteinuria. In addition to controlling the primary causes of kidney disease (e.g., diabetes, hypertension, and glomerulopathies) and using angiotensin-converting enzyme (ACE) inhibitor and angiotensin receptor blocker (ARB) therapy, dietary protein restriction has been evaluated as a strategy for reducing proteinuria and delaying progression of kidney disease.

A number of studies have investigated the effect of protein restriction on disease progression with varying results.[40–42] These conflicting conclusions may be attributable to differences in study design, patient populations, methods to assess kidney function, degrees of protein restriction, and dietary compliance. The MDRD study evaluated the effects of protein restriction and strict BP control on the progression of kidney disease. There was no difference in renal function deterioration comparing patients who received a normal protein diet (1.3 g/kg/day) with those receiving a low-protein (0.58 g/kg/day) diet.[43] In contrast, patients receiving a low-protein diet (0.58 g/kg/day) compared with those receiving a very low-protein diet (0.28 g/kg/day plus keto and amino acid supplementation) had a faster decline in renal function. A secondary analysis of the MDRD study, which accounted for dietary compliance, suggested that patients with severe kidney disease (eGFR <25 mL/minute/1.73 m^2) could benefit from protein restriction of 0.6 g/kg/day.[44] However, a follow-up analysis of the MDRD study found no significant benefit.

KDIGO Guidelines for Evaluation and Management of CKD currently recommend lowering protein intake to 0.8 g/kg/day while avoiding high protein intake (i.e., >1.3g/kg/day) in adults at risk for progression.[1] Avoiding excessive accumulation of uremic toxins, loss of lean body mass, and malnutrition are benefits of appropriate dietary protein restrictions. The potential benefits of protein restriction in patients with CKD must be weighed against the potential adverse effect on overall nutritional status. Malnutrition is prevalent in patients with CKD starting dialysis and is a predictor of mortality in this population.[45]

ANTIHYPERTENSIVE THERAPY

Antihypertensive therapy prevents kidney damage and slows the rate of progression of CKD in both diabetic and nondiabetic patients.[46] In addition, the added benefit of reduced cardiovascular mortality further supports the use of antihypertensive therapy in patients at risk for progressive CKD. Despite what is known about the beneficial effects of BP control in patients with CKD, rates of hypertension control in the predialysis population remain suboptimal.[46]

The 2014 Evidence-Based Guideline for the Management of High Blood Pressure in Adults (commonly referred to as JNC-8) and the KDIGO/Management of Blood Pressure in Chronic Kidney Disease Guideline recommends is a BP less than 140/90 mm Hg in CKD.[46,47] Controversy exists as to the optimal BP target in CKD patients with albuminuria (>30 mg in 24 hours or equivalent). The KDIGO guidelines recommend a BP target of ≤130/80 mm Hg in CKD patients with albuminuria (>30 mg in 24 hours or equivalent) while JNC-8 suggest a target of 140/90 mm Hg for patients with albuminuria. Evidence for further reduction of BP in patients with albuminuria stems mostly from ancillary analysis of larger trials. Results from the MDRD study showed that further lowering of BP to less than 125/75 mm Hg (or a mean arterial pressure <92 mm Hg) was more beneficial than usual BP control in patients with higher rates of urinary protein excretion (>1 g protein/day).[48] The effects of more aggressive BP control on progression of kidney disease were also studied in the African American Study of Kidney Disease and Hypertension (AASK) trial.[49] African Americans aged 18 to 70 years with hypertensive kidney disease (eGFR 20–65 mL/minute/1.73 m^2) were included in this study. A post hoc analysis of the AASK trial found that patients with proteinuria greater than 1 g/day assigned to the low BP target had slower progression to ESRD.[50] Clearly, BP control is important to delay progression of kidney disease, and with the expanding data supporting more aggressive BP lowering in patients with more severe proteinuria, the importance of BP control in this patient population is pivotal in slowing progression of CKD. In light of the concerns with the presence of albuminuria, a target of <140/90 mm Hg is reasonable in the CKD patient with albuminuria.

Among the available classes of antihypertensive agents, ACE inhibitors (ACEIs; e.g., enalapril, captopril, lisinopril) and ARBs (e.g., losartan, irbesartan, candesartan) may afford additional benefits in preserving kidney function. As a result, ACEIs and ARBs are most commonly recommended as first-line treatment options for hypertension in those with CKD, those at risk for CKD (e.g., diabetics), and those with albuminuria by the KDIGO hypertension guidelines.[46] In conditions of decreased eGFR, angiotensin II primarily causes compensatory vasoconstriction of the efferent arteriole, thereby increasing glomerular capillary pressure (P_{GC}) and eGFR (Fig. 28-1). This effect is beneficial in conditions of acute renal failure; however, sustained increases in P_{GC} cause hypertrophy of individual nephrons and progressive kidney disease. ACEI and ARB therapy prevent the chronic increase in glomerular pressure mediated by angiotensin II. Benefits of ACEIs have been demonstrated in patients with diabetes with some degree of proteinuria, suggesting that ACEI use be considered in this population regardless of BP.[46] In patients without diabetes, ACEIs have been shown to reduce BP, decrease proteinuria, and slow the progression of kidney disease when compared with other agents. An initial and mild decrease in eGFR is expected with ACEI therapy; therefore, an increase in SCr of 30% within the first 2 months of therapy is acceptable.[51] Hypotension, acute kidney failure, and severe hyperkalemia are reasons to consider discontinuing therapy (also see Chapter 14, Heart Failure).

Angiotensin II receptor blockers offer similar benefits to ACEIs on the basis of their ability to decrease efferent arteriolar resistance by blockade of the angiotensin type 1 (AT_1) receptor. In patients with type 2 diabetes mellitus, losartan decreased the incidence of a doubling of SCr by 25% and of ESRD by 28% when compared with placebo after a mean of 3.4 years of therapy.[52] Similar effects were observed in the Irbesartan Diabetic Nephropathy Trial (IDNT), with a 23% decreased risk of ESRD observed in patients treated with irbesartan.[53] In both studies, these beneficial effects were independent of reduction in BP. Reduction in the degree of proteinuria has also been demonstrated with candesartan and valsartan.[54] Combination therapy with an ARB and ACEI increases the progression to ESRD, hyperkalemia events, and acute kidney injury risk and should be avoided.[55,56]

Aliskiren is the only available direct renin inhibitor. Its use as monotherapy is unclear and combination with ACEI or ARBs should be avoided.[57] Aliskiren has been associated with reduction in GFR and filtration fraction in patients receiving optimal heart failure therapy.[58]

Calcium-channel blockers have been considered for preventing progression of kidney disease owing to their effects on renal hemodynamics and cytoprotective and antiproliferative properties (prevention of mesangial expansion and renal scarring). Nondihydropyridine agents (e.g., diltiazem and verapamil) have been beneficial in reducing proteinuria when compared with dihydropyridines (e.g., amlodipine), which have been found to worsen proteinuria.[59,60] Dihydropyridine calcium-channel blockers have the effect of increasing albuminuria and should not be used alone in patients with proteinuria, but can be used safely in combination with an ACEI or ARB. Combination therapy with an ACEI and nondihydropyridine agents has resulted in greater reductions in proteinuria in patients with diabetes than with either agent alone, suggesting that it may be rational to use multiple agents in this population.[59]

β-Blockers may offer benefits in the treatment of diabetic nephropathy as demonstrated by the United Kingdom Prospective Diabetes Study, which showed similar effects of atenolol and captopril on decreasing the incidence of albuminuria in patients with diabetes.[61] β-Blockers offer several benefits to CKD patients such as attenuation of excessive sympathetic output and reduction in sudden cardiac death seen in dialysis patients.[62,63] β-Blocker selection should take into account the dialyzability of the drug and/or the risk for drug accumulation.[64]

TREATMENT OF DYSLIPIDEMIA

Low HDL levels, impaired HDL function, higher percentages of oxidized LDL (highly atherogenic LDL molecules), and elevated lipoprotein(a) (highly atherogenic lipoproteins) levels are characteristic alterations of dyslipidemia in CKD that vary from the general population.[65] Similar to the general population, very high cholesterol and elevated non-HDL lipoprotein cholesterol have been associated with increased hospitalizations and CVD mortality in CKD. A meta-analysis of trials have demonstrated an association of statin use with decreased proteinuria and uncertainty with preservation of eGFR.[66] Despite uncertainty of therapy with regard to delaying CKD progression, dyslipidemia should be treated in the kidney disease population. Abnormal lipid metabolism is present in these patients, which predisposes them to the development of atherosclerotic disease. Although the potential for elevated cholesterol profiles in CKD suggests a beneficial role for lipid-lowering therapies in CKD, a varying cardiovascular pathology (e.g., vascular calcification, sympathetic overactivity) in CKD limits the role of lipid-lowering therapies (i.e., statins) across stages of CKD.

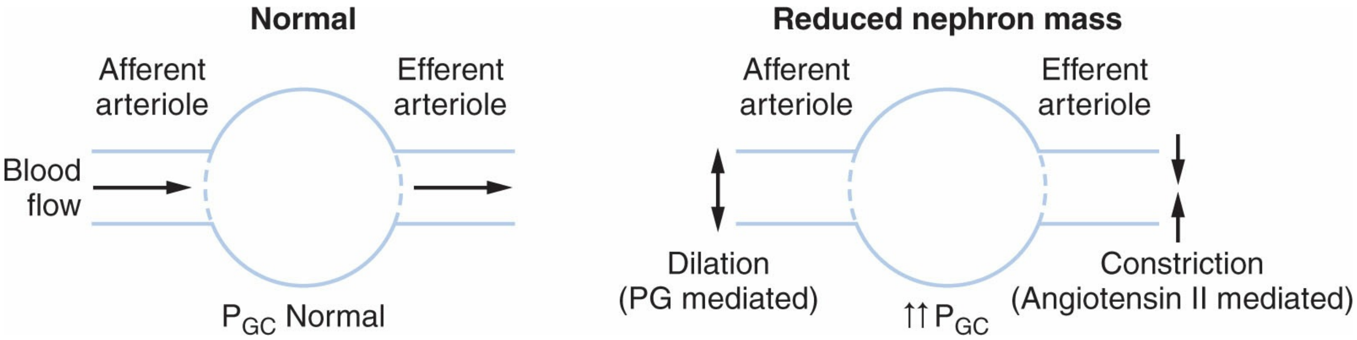

Figure 28-1 Renal hemodynamics are dependent on afferent and efferent arteriolar tone and glomerular capillary pressure (P_{GC}). With reduced nephron mass, afferent arteriolar vasodilation (mediated primarily by prostaglandins [PG] I_2 and E_2) and efferent arteriolar constriction (mediated primarily by angiotensin II) occur within remaining functioning nephrons to compensate. This leads to an increase in blood flow, intraglomerular capillary filtration pressure (P_{GC}), and hyperfiltration (increased single-nephron effective GFR). Sustained increases in plasma flow and hydrostatic pressure lead to hyperfiltration injury and glomerular sclerosis. With time, these changes contribute to continued loss of nephron function (i.e., progression of kidney disease). Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers prevent vasoconstriction of the efferent arteriole and reduce the P_{GC}.

The KDIGO Clinical Practice Guidelines for Lipid Management in CKD released guidance for the management of dyslipidemia. Similar to the general population, statin therapy is recommended irrespective of baseline LDL cholesterol levels in non-dialysis–dependent CKD patients.[67] For CKD patients ≥50 years and not on dialysis, KDIGO recommends treatment with a statin or statin/ezetimibe combination. CKD patients aged 18 to 49 years with additional CVD risk factors such as known coronary disease (MI or coronary revascularization), diabetes, prior ischemic stroke, or estimated 10-year coronary heart disease risk >10% are recommended to initiate statin therapy. A strategy of "fire-and-forget" is suggested for statin therapy where measurement of LDL cholesterol is avoided unless results would alter management. However, recent commentary of the KDIGO guidelines suggest measuring lipids 6 weeks to 3 months after initiation of a statin in order to identify patients with an inadequate response to moderate-intensity statins and who require dose titration as a reasonable approach to lipid monitoring.[68]

The Study of Heart and Renal Protection (SHARP) assessed the effect of lowering LDL cholesterol in 9,270 CKD patients with ezetimibe 10 mg daily and simvastatin 20 mg daily or matching dummy placebo tablets for an average of 5 years. Mean eGFR was 27 mL/minute/1.73 m^2; 3,023 (33%) were on dialysis and 2,094 (23%) had diabetes. Key outcomes were reductions in major atherosclerotic events and kidney disease progression. SHARP results showed a 25% risk reduction in major atherosclerotic events. However, there was no effect on the progression of kidney disease.[69] The significance found with the combined primary outcome was most likely driven by significant reductions in non-hemorrhagic stroke and coronary revascularization. Although the study was not powered to detect differences within subgroups, subgroup analysis did not find a statistically significant benefit in patients receiving dialysis.

The cardiovascular benefits of statin use observed in the general population have not consistently been demonstrated in the dialysis populations, possibly owing to the multifactorial pathogenic process of CVD in those with kidney disease (e.g., the presence of vascular calcification).[65] KDIGO lipid guidelines recommend against treatment with a statin in CKD 5D patients unless initiated prior to the start of dialysis.

The Die Deutsche Diabetes Dialyse Studie (4D) and AURORA are two large multicenter, double blind, placebo-controlled, randomized controlled trials that examined the effects of lowering the level of LDL-C on cardiovascular events and mortality with atorvastatin or rosuvastatin, respectively. Both studies with a combined patient population of greater than 4,000 demonstrated significant reductions in LDL cholesterol levels; however, neither produced statistically significant reductions in the primary outcome measure. The results of these studies along with the negative effects in dialysis patients from the SHARP study have largely driven KDIGO recommendations to avoid initiating statin therapy in dialysis patients.[67]

KDIGO recommend that statins be prescribed in preference to fibrates. Fibrates should be used cautiously in patients with CKD; all agents in this class are metabolized by the kidney and are eliminated primarily via the kidney, which may lead to an increased risk of rhabdomyolysis. However, fibric acid derivatives may be considered in patients presenting with very high triglycerides (>1,000 mg/dL). Gemfibrozil is cautioned in mild to moderate kidney dysfunction and not recommended in severe kidney impairment.[70]

END-STAGE RENAL DISEASE (CHRONIC KIDNEY DISEASE 5D)

Clinical Signs and Symptoms

During CKD 4 and 5, patients may develop the more severe signs and symptoms associated with advanced kidney disease, often referred to as uremic syndrome. The manifestations and metabolic consequences of advanced kidney disease are listed in Table 28-7. These manifestations certainly may develop in the earlier stages of CKD, underscoring the importance of early intervention, but they become more prominent as the disease worsens. The pathogenesis of these disorders has been attributed, in part, to the accumulation of uremic toxins. The search for uremic toxins has led to the identification of nitrogenous compounds that are consistently observed in the serum of patients with kidney disease. A cause and effect relationship between these compounds and the clinical manifestations of uremia has not been clearly established.[71]

Treatment

DIALYSIS AND TRANSPLANTATION

As ESRD becomes inevitable, the appropriate dialysis modality must be selected on the basis of patient preference and options for vascular access for HD or peritoneal access for PD. Early planning for dialysis therapy and timely initiation may lower patient morbidity and mortality. (Indications for dialysis and considerations in selection of modality are discussed in Chapter 30, Renal Dialysis.) Kidney transplantation is an option for all patients with ESRD without specified contraindications if a suitable organ match is available (see Chapter 34, Kidney and Liver Transplantation).

PHARMACOTHERAPY

Pharmacotherapy in patients with ESRD requires interventions to manage comorbid conditions and secondary complications of CKD. The extent of medication use, including medications administered during dialysis therapy, contributes to the potential for drug interactions, adverse reactions, and nonadherence to therapy.[72] The effect of decreased kidney function on absorption, distribution, metabolism, and elimination of pharmacologic agents, in addition to the contribution of dialysis to drug removal, further complicates pharmacotherapy in this population (see Chapter 31, Dosing of Drugs in Renal Failure). Appropriate pharmacotherapeutic management includes choice of rational agents based on the indication, a regular comprehensive review of all medications, and frequent reevaluation to adjust regimens relative to kidney function.

G.B.’s abnormal values for SCr, BUN, serum potassium, magnesium, phosphate, uric acid, CO_2 content, hemoglobin, are all consistent with kidney disease and its associated complications. Assuming relatively stable kidney function (i.e., no acute changes in kidney function), her eGFR is approximately 21 mL/minute/1.73 m^2 based on the MDRD equation, placing her in CKD category 4 (eGFR 15–29 mL/minute/1.73 m^2). As the eGFR declines to the degree observed in G.B., normal regulation of fluids and electrolytes is impaired. Elevations in SCr, BUN, sodium, potassium, magnesium, phosphate, and uric acid as well as signs of fluid accumulation are observed. G.B.’s serum potassium is slightly elevated and the risk of hyperkalemia increases with CKD.[73] The substantial degree of proteinuria observed in G.B. is consistent with advanced glomerular damage. Volume overload from continued intake and decreased sodium and water excretion leads to weight gain, hypertension, and edema. Metabolic acidosis results from impaired synthesis of ammonia by the kidney, which normally buffers hydrogen ions and facilitates acid excretion. Anemia associated with CKD is caused primarily by decreased EPO production by the kidneys, but it also can be caused by shortened half-life of RBCs from uremia, and iron deficiency. G.B.’s recent onset of nausea and malaise may be a consequence of the accumulation of uremic toxins (azotemia) from the decline in kidney function.

CASE 28-1

QUESTION 1: G.B. is a 44-year-old, African American woman (weight, 175 lb; height, 5 ft. 5 inches) with a 20-year history of type 2 diabetes mellitus. She presents to the diabetes clinic for her quarterly checkup. She has been noncompliant with regular appointments, and her blood glucose has generally remained greater than 200 mg/dL on prior evaluations, with a hemoglobin A_{1c} of 10.1% (goal, <7%) 2 months ago. Lately G.B. complains of general nausea, malaise, and poor appetite. She has been treated for peptic ulcer disease for the past 6 months. The workup reveals the following pertinent laboratory values:

Serum sodium (Na), 143 mEq/L
Potassium (K), 5.3 mEq/L
Chloride (Cl), 106 mEq/L
CO_2 content, 18 mEq/L
SCr, 2.9 mg/dL
BUN, 63 mg/dL
Random blood glucose, 289 mg/dL

Physical examination reveals a BP of 160/102 mm Hg, 2+ pedal edema, and mild pulmonary congestion, and a 10-lb weight gain. Additional laboratory studies show the following results:

Serum phosphate, 6.6 mg/dL
Calcium (Ca), 8.8 mg/dL
Albumin (Alb), 3.6 g/dL
Magnesium (Mg), 2.8 mEq/L
Uric acid, 8.8 mg/dL

Hematologic studies show the following results:

Hematocrit (Hct), 28%
Hemoglobin (Hgb), 9.3 g/dL
White blood cell (WBC) count, 9,600/μL

Platelet count, 155,000/µL

RBC indices are normal. G.B.'s reticulocyte count is 0.5%. Her UA showed 4+ proteinuria, later quantified as a urinary albumin of 700 mg/24 hours. What subjective and objective data in G.B. are consistent with a diagnosis of advanced kidney disease?

CASE 28-1, QUESTION 2: What is the cause of G.B.'s advanced kidney disease?

Given G.B.'s presentation, her kidney disease is most likely caused by diabetic nephropathy from her 20-year history of type 2 diabetes mellitus. Poor compliance with regular appointments, elevated glucose concentration and hemoglobin A_{1c} values, and

---

albuminuria serve as the primary cause. Diabetic nephropathy rarely develops within the first 10 years after the onset of type 1 diabetes; however, 5% to 20% of patients with type 2 diabetes have some degree of albuminuria at diagnosis. The annual incidence is greatest after approximately 20 years' duration of diabetes and declines thereafter. G.B. fits this pattern in that she has diabetic nephropathy after a 20-year history of diabetes, although her nephropathy was likely evident several years previously. African Americans, Native Americans, and Hispanics have an increased risk of developing ESRD from diabetes relative to whites.[5]

Diabetic nephropathy is a microvascular complication of diabetes resulting in albuminuria, hemodynamic changes in kidney microcirculation, glomerular structural changes, and a progressive decline in kidney function. Diabetic nephropathy develops in approximately one-third of all patients with type 1 and type 2 diabetes.[72] Because type 2 diabetes is more prevalent, these patients account for most diabetic patients starting dialysis. With the increased prevalence of diabetes and the increase in life expectancy of this population, it is likely that diabetic nephropathy will remain the leading cause of ESRD in the United States. Whereas most research has focused on the pathophysiology, prevention, and treatment of diabetic nephropathy in type 1 diabetes, it is reasonable to extrapolate available evidence on prevention of diabetic nephropathy to the population with type 2 diabetes.[74]

The exact mechanisms leading to the development of diabetic nephropathy are not clearly defined; however, several predictive factors for the development and progression of kidney damage have been identified. These include elevated BP, plasma glucose, glycosylated hemoglobin, and cholesterol; smoking; advanced age; male sex; and, potentially, high protein intake.[75] Insulin deficiency and increased ketone bodies have also been proposed as contributors to the pathogenesis. Advanced glycosylation end products (AGE) that form in conditions of hyperglycemia have also been implicated as a cause of end-organ damage. The accumulation of multiple AGE is associated with the severity of kidney disease in patients with diabetic nephropathy.[76] A genetic predisposition exists in that higher rates of diabetes and nephropathy, hypertension, cardiovascular events, albuminuria, and elevated BP have been observed in relatives of patients with type 2 diabetes.[77] Certain genes and polymorphisms have also been associated with the development of diabetic nephropathy, and further exploration into this area may prove beneficial in identifying high-risk patients.[78,79]

CASE 28-1, QUESTION 3: What is the significance of G.B.'s albuminuria?

Albuminuria, the earliest sign of kidney involvement in patients with diabetes mellitus, correlates with the rate of progression of kidney disease. Albuminuria not only indicates renal damage but is also a powerful predictor of cardiovascular morbidity and mortality.[1] For most patients, eGFR begins to decline once proteinuria is established. Because of this association, annual testing for the presence of microalbuminuria is indicated in patients who have had type 1 diabetes for more than 5 years and in all patients with type 2 diabetes starting at diagnosis.[75] The presence of albuminuria indicates irreversible kidney damage. G.B. has likely reached the point at which such damage is inevitable because her urinary protein exceeds ranges normally observed at the earlier stages of kidney disease. G.B.'s current laboratory data suggest that she has substantial kidney disease and has developed associated complications of the disease. Although progression to ESRD is generally beyond prevention at this stage, appropriate intervention can slow the progression to ESRD for G.B. Progressive diabetic nephropathy consists of proteinuria of varying severity occasionally leading to nephrotic syndrome with hypoalbuminemia, edema, and an increase in circulating LDL cholesterol as well as progressive azotemia.

CASE 28-1, QUESTION 4: How should G.B.'s kidney disease be managed?

Management

Because reversal of G.B.'s kidney disease is not possible, the primary goals are to delay the need for dialysis therapy as long as possible and to manage complications. The three main risk factors for the progression of incipient nephropathy to clinical diabetic nephropathy are poor glycemic control, systemic hypertension, and high dietary protein intake (>1.3 g/kg/day). G.B.'s current random blood glucose concentration of 289 mg/dL, history of elevated glucose on prior visits, and elevated hemoglobin A_{1c} indicate poorly controlled diabetes, which will accelerate the progression of diabetic nephropathy and time to ESRD. Thus, her blood glucose concentrations should be maintained within target goals while avoiding hypoglycemia. G.B.'s elevated BP is likely the result of kidney disease and changes in intravascular volume; reduction in BP may prevent further damage to functioning nephrons and slow the progression to ESRD. Similarly, reductions in dietary protein intake (dietary protein intake of approximately 0.8 g/kg body weight/day) should be initiated in an attempt to reduce the rate of further progression, although this needs to be evaluated in the context of her overall nutritional status.

INTENSIVE GLUCOSE CONTROL

Strict glycemic control can improve diabetic management, reduce proteinuria, and slow the rate of decline in eGFR. The Diabetes Control and Complications Trial (DCCT), a randomized clinical trial of type 1 diabetic patients (n = 1,441), demonstrated that maintaining fasting blood glucose concentrations between 70 and 120 mg/dL, with postprandial blood glucose concentrations less than 180 mg/dL, delayed the onset and progression of microvascular diseases such as diabetic nephropathy and reduced the risk of CKD. Patients were randomly assigned to receive either conventional insulin treatment (one to two insulin doses a day) or intensive treatment (three or more insulin doses a day). After a mean follow-up of 6.5 years, the intensive insulin regimen reduced the overall risk of moderately increased albuminuria by 39% and severely increased albuminuria by 54%. Unfortunately, stricter glycemic control was associated with an increased incidence of hypoglycemic episodes.[80]

The UK Prospective Diabetes Study (UKPDS) demonstrated the beneficial effects of intensive glycemic control in patients with type 2 diabetes (n = 3,867). During a 10-year treatment period, intensive glucose control (fasting glucose <108 mg/dL) with either insulin or an oral sulfonylurea reduced microvascular complications (e.g., retinopathy and nephropathy), including albuminuria by 33%, when compared with conventional dietary therapy (fasting glucose <270 mg/dL). Similar to the DCCT, intensive treatment groups in the UKPDS experienced more hypoglycemic reactions.[81]

Additionally diabetes trials such as Action to Control Cardiovascular Risk in Diabetes (ACCORD) and Action in Diabetes and Vascular Disease: Preterax and Diamicron MR Controlled Evaluation (ADVANCE) evaluated the macrovascular and microvascular outcomes associated with intensive glucose control in type 2 diabetics. The ACCORD trial showed a 21% reduction in the development of moderately increased albuminuria cases and a 32% reduction in severely increased albuminuria cases.[82] In the ADVANCE trial, there was a 9% reduction in moderately increased albuminuria and 30% reduction in progression to

---

severely increased albuminuria.[83] Similar to other studies, severe hypoglycemia, although uncommon, was more common in the intensive-control group.[83]

KDIGO Guidelines for Evaluation and Management of CKD recommend a hemoglobin A_{1c} of approximately 7% to prevent or delay progression of the microvascular complications of diabetes including diabetic kidney disease. Targeting an A_{1c} less than 7% increases patients' risk of experiencing hypoglycemia and without improvements in cardiovascular outcomes and should be avoided. In CKD patients with diabetes and comorbidities or a limited life expectancy and risk of hypoglycemia, a target A1c above 7.0% is suggested.[1]

G.B. will benefit from a multifactorial approach addressing glycemic control and hypertension to slow her progression of CKD from DM. Appropriately dosed oral and/or insulin therapy can achieve these goals despite her advanced kidney disease. G.B. should be counseled on appropriate techniques for home glucose monitoring, particularly given her history of noncompliance. Compliance with this regimen will require motivation as well as encouragement from G.B.'s family and health care providers. (See Chapter 53, Diabetes Mellitus, for a more complete discussion of intensive insulin therapy and counseling.)

ANTIHYPERTENSIVE THERAPY

Systemic hypertension usually occurs with the development of normal to moderately increased albuminuria in patients with type 1 diabetes. It is also present in about one-third of patients at the time of diagnosis of type 2 diabetes, and hastens the progression of kidney disease in both groups. The coexistence of these disorders further increases the risk of cardiovascular events. Hypertension may be a result of underlying diabetic nephropathy and increased plasma volume or increased peripheral vascular resistance. Regardless of the etiology, virtually any level of untreated hypertension (either systemic or intraglomerular) is associated with a reduction in eGFR. As such, the control of systemic and intraglomerular BP is perhaps the single most important factor for retarding the progression of kidney disease and has been shown to increase life expectancy in patients with type 1 diabetes.[84]

Patients with diabetes and hypertension exhibit elevated systemic vascular resistance and increased vasoconstriction from angiotensin II, which are in large part responsible for the glomerular damage characteristic of diabetic nephropathy. Although the management of hypertension with virtually any agent can attenuate the progression of kidney disease, ACEIs, which inhibit the synthesis of angiotensin II, and ARB, which block angiotensin II AT_1 receptors, are preferred owing, in part, to the effects of these agents on renal hemodynamics (Fig. 28-1). KDIGO guidelines recommend ACEI or ARB for the treatment of hypertension in all CKD patients with AER >300 mg/24 hour and diabetic CKD adults with AER ≥30 mg/24 hour.[46] JNC-8 recommends ACEI or ARB for all CKD patients regardless of race and with an ACR >30 mg/g to improve kidney outcomes.[47] Reductions in proteinuria and a decreased rate of decline in eGFR have been observed with ACEIs and ARB in patients with type 1 and type 2 diabetes.[46] As a result of these and other studies, ACEIs or ARB should be considered for all patients with diabetes and AER >30 mg/24 hour, even if their BP is normal.[1,47] ACEI and ARBs have similar efficacy in BP reduction when dosed accordingly. Combination therapy is associated with an increased risk of dialysis and doubling of SCr and should be avoided.[56]

Additionally, spironolactone in combination with an ACEI or ARB lowers albuminuria independent of BP control in patients with type 2 diabetes.[85] However, the risk of hyperkalemia increases significantly limiting the benefit of this therapy. Aliskiren, an oral direct renin inhibitor, has demonstrated a reduction in albuminuria when added to losartan. However, additional studies have resulted in early termination because of increased risk of adverse events and lack of demonstrable benefits.[57] The role of aliskiren is uncertain and benefits do not appear to compare with ACEI and ARBs. The primary goal in G.B. is to delay development of ESRD and to reduce the risk of cardiovascular complications and death. Treatment with an ACEI (e.g., ramipril) should be initiated, because she has substantial albuminuria (700 mg/day) and an elevated BP. An ARB (e.g., losartan) is a reasonable alternative to an ACEI in patients with ACEI–induced cough or other adverse effects that do not cross-react with an ARB. The initial product selected is generally based on tolerance to therapy and cost. A goal BP for G.B., given the fact that she has diabetes and kidney disease, is a BP less than 130/80 mm Hg,[1] 140/90 mg may be reasonable goal as well.[46] Because the beneficial effects of ACEI therapy occur over the course of months to years, G.B. must be monitored on a long-term basis for changes in kidney function and albuminuria and for side effects of therapy, such as hyperkalemia. A moderate increase in SCr is acceptable with initiation of therapy with ACEIs or ARBs. Contraindications for the use of ACEIs and ARBs include bilateral kidney artery stenosis and pregnancy. The risk of hyperkalemia must also be weighed against the potential beneficial effects of these agents.

Some evidence suggests that a nondihydropyridine calcium-channel blocker (e.g., diltiazem, verapamil) may be beneficial alone or in combination with an ACEI.[51] Diuretics may be considered for patients with diabetic nephropathy and edema, depending on their degree of kidney function. For patients with kidney disease as extensive as that observed in G.B. (eGFR <30 mL/minute/1.73 m^2), loop diuretics are generally preferred because, unlike thiazide diuretics, they may retain their effect at this reduced eGFR level (see Chapter 27, Fluid and Electrolyte Disorders, and Chapter 9, Essential Hypertension). Other antihypertensive agents may be considered based on response to initial therapy and changes in kidney function. Currently, clinical studies are examining the use of an aldosterone blocker (spironolactone) and a selective aldosterone blocker (eplerenone) for use in patients with diabetic nephropathy and overt proteinuria on maximal doses of both an ACEI and an ARB. The antiproteinuric effect of these agents has been confirmed by several studies, but the potential increased risk for hyperkalemia when adding these agents to patients already taking an ACEI and ARB warrants further evaluation of their use. The effect on slowing progression of kidney disease has not been evaluated with these agents.[85] Additionally, G.B. should be counseled regarding an exercise program compatible with her cardiovascular health and tolerance.

DIETARY PROTEIN RESTRICTION

High protein consumption accelerates the progression of diabetic nephropathy, presumably because of increased glomerular hyperfiltration and intraglomerular pressure. In patients with overt albuminuria, some evidence indicates that the rate of decline in eGFR, as well as urinary albumin excretion, can be blunted by restricting protein intake to 0.8 g/kg/day and maintaining an isocaloric diet.[44] Limited evidence indicates, however, a beneficial role of dietary protein restriction in diabetic patients with microalbuminuria. Nonetheless, given the potential benefits to delay progression of kidney disease, G.B. should be advised to maintain an isocaloric diet with a protein intake of 0.8 g/kg/day (approximately 10% of daily calories).[1] Because the typical Western diet is high in protein, some patients may have difficulty complying with such a low-protein diet because of its perceived unpalatability. Intervention by a dietitian is recommended to design a feasible dietary regimen limited in protein, yet consistent with nutritional requirements in a diabetic patient.

FLUID AND ELECTROLYTE COMPLICATIONS

Sodium and Water Retention

CASE 28-1, QUESTION 5: Assess G.B.'s sodium and water balance. What interventions may be used to address this problem?

As illustrated in G.B., patients in the latter stages of CKD commonly retain sodium and water. This is supported by G.B.'s elevated BP, 2+ pedal edema, and mild pulmonary congestion. Sodium and water retention also lead to weight gain. Early in the course of CKD, glomerular and tubular adaptive processes develop as an increase in the fractional excretion of sodium (FE_{Na}). These mechanisms enable patients to maintain relatively normal sodium and water homeostasis. As G.B.'s normal serum sodium concentration indicates, this value is of little use in establishing the diagnosis of total body sodium and fluid excess because retention of sodium and water usually occurs in an isotonic fashion, leaving the serum sodium concentration relatively normal. Eventually, patients with advanced kidney dysfunction exhibit signs of sodium and fluid retention because sodium balance is maintained at the expense of increased extracellular volume, which results in hypertension. Expansion of blood volume, if not controlled, can cause peripheral edema, heart failure, and pulmonary edema. Thus, management of sodium and water retention is essential. To achieve control, most patients with advanced kidney disease are placed on sodium restriction (2 g/day) and fluid restriction (approximately 1–2 L/day). These restrictions will depend on the current dietary intake, extent of volume overload, and urine output, and should be altered according to the special needs of the patient.

Because some patients with advanced kidney disease produce normal amounts of urine, whereas others may produce less (or no urine for HD patients), fluid restrictions must be based on urine output. Diuretic therapy, usually with loop diuretics (e.g., furosemide, bumetanide, torsemide), is often required. Combination therapy with two different types of diuretics (i.e., loop and thiazide) may be successful in patients resistant to a single agent; however, limitations in efficacy of diuretics exist under certain conditions (e.g., a reduced eGFR and hypoalbuminemia), and these situations must be considered when designing a diuretic regimen. Thiazide diuretics as single agents are generally not effective when the eGFR is less than 30 mL/minute/1.73 m^2, as in G.B. The possible exception is use of the thiazide-like diuretic, metolazone, which may retain its effect at reduced eGFRs.[46] As kidney failure progresses, manifestations of excess fluid accumulation (i.e., edema, uncontrollable hypertension) develop that are resistant to more conventional interventions and dialysis will be required to control volume status.

Hyperkalemia

CASE 28-1, QUESTION 6: G.B. has a serum potassium concentration of 5.3 mEq/L. Describe the mechanisms by which potassium imbalance occurs in patients such as G.B. who have progressive CKD.

Hyperkalemia can result from a combination of factors, including diminished kidney potassium excretion, redistribution of potassium into the extracellular fluid owing to metabolic acidosis, and excessive potassium intake. In G.B., all these mechanisms are likely to be contributing to hyperkalemia.

Potassium normally is filtered at the glomerulus and undergoes nearly complete reabsorption throughout the kidney tubule. Distal tubular secretion is the primary mechanism by which potassium is excreted in the urine. A variety of factors affect this distal secretion of potassium, including aldosterone, sodium load presented to the distal reabsorptive site, hydrogen ion secretion, the amount of nonresorbable anions, urinary flow rate, diuretics, mineralocorticoids, and potassium intake.[86] Serum potassium concentrations are relatively well maintained within normal limits in patients with CKD. At eGFR greater than 10 mL/minute/1.73 m^2, hyperkalemia is rare without an endogenous or exogenous load of potassium. This balance is maintained despite a decreasing nephron population and an overall drop in eGFR because the remaining nephrons undergo adaptive changes to enhance the distal tubular secretion of potassium per nephron (i.e., increased fractional excretion of potassium, FE_K).[87] GI excretion of potassium is also important because increased GI excretion and fecal losses may account for up to 35% of the daily potassium loss in patients with severe kidney disease. G.B.'s eGFR of 21 mL/minute/1.73 m^2 is above the threshold value for adequate potassium homeostasis. G.B. should be carefully observed for manifestations of hyperkalemia as her kidney disease progresses.

Additional factors that alter potassium homeostasis include metabolic or respiratory acidosis. Acidemia can cause a redistribution of intracellular potassium to the extracellular fluid. G.B. has metabolic acidosis as indicated by serum bicarbonate of 18 mEq/L. This condition may account for her mildly elevated potassium concentration. Correction of metabolic acidosis could lower her potassium concentration. For each 0.1-unit change in blood pH, an inverse approximately 0.6-mEq/L change in the serum potassium concentration occurs (see Chapter 26, Acid–Base Disorders).

G.B. is not taking any drugs that could contribute to hyperkalemia, although the influence of ACEIs and ARB must be considered because they are now advocated for G.B. to delay progression of kidney disease. Potassium-sparing diuretics triamterene and amiloride should be avoided and spironolactone used with caution in patients with severe CKD because they decrease tubular secretion of potassium.

CASE 28-1, QUESTION 7: Is treatment of G.B.'s potassium indicated? How should severe hyperkalemia be managed?

Treatment of hyperkalemia depends on the serum concentration of potassium as well as the presence or absence of symptoms and electrocardiographic (ECG) changes. Manifestations of hyperkalemia include weakness, confusion, and muscular or respiratory paralysis. These symptoms may be absent, especially if hyperkalemia develops rapidly. Early ECG changes include peaked T waves, followed by decreased R-wave amplitude, widened QRS complex, and a prolonged P-R interval. These changes may progress to complete heart block with absent P waves and, finally, a sine wave. Ventricular arrhythmias or cardiac arrest may ensue if no effort to lower serum potassium is initiated. However, with a potassium level less than 6 mEq/L, G.B. is unlikely to be experiencing ECG changes.

G.B. has a mild elevation in potassium to 5.3 mEq/L; therefore, no specific treatment is required. Generally, treatment is unnecessary if the potassium concentration is less than 6.5 mEq/L and there are no ECG changes. Although this serum potassium concentration does not require immediate intervention, close monitoring for hyperkalemia and its manifestations is necessary. This would be particularly important after starting ACEI therapy, which can contribute to development of hyperkalemia by decreasing aldosterone production. If potassium concentrations rise above 6.5 mEq/L, and especially if they are accompanied by neuromuscular symptoms or changes in the ECG, treatment should be instituted.

Goals of therapy include prevention of adverse events related to excessive potassium and reduction of serum potassium

---

concentrations to a relatively normal range. Chronic management involves prevention of hyperkalemia by limiting potassium intake and avoiding the use of agents that could elevate potassium levels. This requires regular monitoring of potassium concentrations. Acute management involves reversal of cardiac effects with calcium administration and reduction of serum potassium. The latter can be achieved by shifting potassium intracellularly with administration of glucose and insulin, β-adrenergic agonists, or alkali therapy (if metabolic acidosis is a contributing factor) and by removing potassium using exchange resins or dialysis (see Chapter 27, Fluid and Electrolyte Disorders).

Metabolic Acidosis

CASE 28-1, QUESTION 8: Assess G.B.'s acid–base status. How should her acid–base disorder be managed?

G.B.'s low blood CO_2 content and high chloride concentration are consistent with metabolic acidosis. Normal buffering of hydrogen ions by the bicarbonate–carbonic acid system as well as other extracellular and intracellular buffers, including proteins, phosphates, and hemoglobin, is essential for maintaining normal acid–base balance (i.e., normal pH). Normal metabolism of ingested food produces approximately 1 mEq/kg of metabolic acid daily, which must be excreted by the kidneys (primarily as ammonium ion) to maintain acid–base balance. The kidney is responsible for reabsorption of bicarbonate and excretion of hydrogen ions through buffering by ammonia (produced by the kidney) and filtered phosphates. Reduced bicarbonate reabsorption and impaired production of ammonia by the kidneys are the major factors responsible for development of metabolic acidosis in advanced kidney disease. As nephron function declines, production of ammonia is increased to compensate for a decrease in secretion of hydrogen ions; however, once the maximal capacity for ammonia production is reached, acidosis develops. Mild hyperchloremia is generally observed in the earlier stages. As kidney disease progresses, metabolic acidosis with an elevated anion gap is observed owing to accumulation of organic acids (see Chapter 26, Acid–Base Disorders). Bone carbonate stores serve as a source of alkali, but with time cannot compensate for changes in acid–base balance. Metabolic acidosis can contribute to bone disease by promoting bone resorption, and it may also influence nutritional status by decreasing albumin synthesis and promoting a negative nitrogen balance.[88]

G.B.'s mild acidosis should be treated with a goal of normalizing the plasma bicarbonate concentration or at least achieving bicarbonate levels of at least 22 mEq/L. Treatment includes use of preparations containing sodium bicarbonate or sodium citrate. Each 650-mg tablet of sodium bicarbonate provides 8 mEq of sodium and 8 mEq of bicarbonate. Shohl's solution and Bicitra contain 1 mEq of sodium and the amount of citrate or citric acid to provide 1 mEq of bicarbonate/mL. These latter agents may be used in patients who experience excessive GI distress with sodium bicarbonate because of production and elimination of carbon dioxide. If a patient such as G.B. is sodium and fluid overloaded, it is important to consider that sodium bicarbonate can exacerbate this problem. Polycitra, or potassium citrate, is a possible alternative; however, the potassium content limits its use in patients with more severe kidney disease. Citrate also promotes aluminum absorption and should not be used in patients taking aluminum-containing agents. The amount of bicarbonate supplementation to achieve a bicarbonate of 22 mEq/L can range from 0.3 to 1 mEq/kg/day.[89–91] Typical starting regimens can be two to four 650mg sodium bicarbonate tablets/days (divided into two to three doses). Afterwards, doses should be titrated to desired bicarbonate levels. Equations based on the serum bicarbonate level are available if an immediate correction of the metabolic acidosis is warranted.[88]

Once dialysis therapy is initiated in patients with kidney disease, IV and oral supplementation with bicarbonate or citrate or citric acid preparations is generally not required. At this point, dialysis therapy is used to chronically manage metabolic acidosis through use of dialysate baths containing bicarbonate. Bicarbonate is added to the dialysate solution and is delivered through the process of diffusion from the dialysate bath into the plasma (see Chapter 30, Renal Dialysis). If dialysis therapy is initiated in G.B., the continued need for oral bicarbonate supplementation should be reassessed.

Other Electrolyte and Metabolic Disturbances of Chronic Kidney Disease

CASE 28-1, QUESTION 9: What other electrolyte and metabolic disturbances are exhibited by G.B.?

G.B.’s hyperphosphatemia is a result of decreased phosphorus elimination by the kidneys (see Case 28-3, Question 2, for a more detailed discussion of hyperphosphatemia). The KDIGO guidelines for Diagnosis, Evaluation, Prevention, and Treatment of CKD Mineral and Bone Disorder recommend reducing dietary phosphorus to 800 to 1,000 mg/day while maintaining adequate nutritional needs.[92] Phosphorus-containing laxatives and enemas should also be avoided. Hyperphosphatemia is associated with low serum calcium concentrations.

The mild degree of hypermagnesemia seen in G.B. is a common finding in patients with CKD owing to decreased elimination of magnesium by the kidney. Magnesium is eliminated by the kidney to the extent required to achieve normal serum magnesium concentrations until eGFR is less than 30 mL/minute/1.73 m^2. Serum magnesium concentrations less than 4 mEq/L rarely cause symptoms. Higher concentrations can lead to nausea, vomiting, lethargy, confusion, and diminished tendon reflexes, whereas severe hypermagnesemia may depress cardiac conduction. The risk of hypermagnesemia can be reduced by avoiding magnesium-containing antacids and laxatives and by use of a magnesium-free dialysate in patients with CKD 5D.

G.B. also has mild hyperuricemia. Asymptomatic hyperuricemia frequently develops in patients with kidney disease owing to diminished urinary excretion of uric acid. In the absence of a history of gout or urate nephropathy, asymptomatic hyperuricemia does not require treatment.

ANEMIA OF CHRONIC KIDNEY DISEASE

CASE 28-1, QUESTION 10: What findings in G.B. are consistent with the diagnosis of anemia of CKD, and what is the etiology of this disorder?

G.B.'s hemoglobin of 9.3 g/dL is substantially lower than the normal range for premenopausal females, indicating that she has anemia. Her normal RBC indices suggest her red cells are of normal size, but the absence of an elevated reticulocyte count suggests an impaired bone marrow response for her degree of anemia. Her recent history of peptic ulcer disease may also have contributed to the observed drop in hemoglobin as a result of blood loss. Her complaint of general malaise is consistent with the symptoms of anemia.

Characteristics and Etiology

Anemia, which affects most patients with CKD, is caused by a decreased production of EPO, a glycoprotein that stimulates RBC production in the bone marrow and is released in response to hypoxia. Approximately 90% of the total EPO is produced in the peritubular cells of the kidney; the remainder is produced by the liver. EPO concentrations in patients with kidney failure are lower than in individuals with normal kidney function who have the same degree of anemia and the same stimulus for EPO production and release.[93]

Anemia appears as early as CKD 3 and is characterized by normochromic (normal color) and normocytic (normal size) RBCs unless a concomitant iron, folate, or vitamin B_{12} deficiency exists. A direct correlation between eGFR and hematocrit has been demonstrated, with a 3.1% decrease in hematocrit for every 10 mL/minute/1.73 m^2 decline in eGFR.[94] A higher prevalence of anemia occurs in the population with an eGFR less than 60 mL/minute/1.73 m^2.[1] Pallor and fatigue are the earliest clinical signs, with other manifestations developing as anemia progresses with declining kidney function. A significant consequence of anemia is development of left ventricular hypertrophy (LVH), further contributing to cardiovascular complications and mortality in patients with CKD. LVH has been observed in approximately 30% of patients with eGFR 50 to 75 mL/minute/1.73 m^2 (CKD 2 and 3) and in up to 74% of patients at the start of dialysis.[95] These findings support the need for early and aggressive treatment of anemia of CKD before the development of CKD 5.

A complete workup for anemia of CKD is recommended for patients with an eGFR of less than 60 mL/minute/1.73 m^2.[93] This workup includes a complete blood count including hemoglobin, assessment of iron indices with correction if iron deficiency is present, and evaluation for sources of blood loss, such as bleeding from the GI tract. This workup should be done at least twice per year for the stage of CKD because of the association between anemia and the progressive decline in eGFR.[93]

IRON STATUS

Iron deficiency substantially contributes to anemia development and is the primary cause of erythropoiesis-stimulating agent (ESA) hyporesponsiveness; thus, iron status assessment is essential before considering or initiating erythropoietic therapy. The two tests that best evaluate iron status are the transferrin saturation percent (TSAT) and serum ferritin.[93] Transferrin is a carrier protein, and its concentration depends on nutritional status. The TSAT indicates the saturation of the protein transferrin with iron and is determined as follows (Eq. 28-6):

$$\%\ \text{TSAT} = \frac{\text{serum iron (mcg/dL)}}{\text{TIBC (mcg/dL)}} \times 100 \qquad \text{(Eq. 28-6)}$$

where TIBC is the total iron-binding capacity of the transferrin protein. The TSAT is considered iron readily available for RBC production. Serum ferritin is a marker for iron reserves, which are stored primarily in the reticuloendothelial system (e.g., liver, spleen). The goal of iron replacement therapy is to maintain the TSAT greater than 30% and a serum ferritin greater than 500 ng/mL for CKD to provide sufficient iron for erythrocyte production. Values below these targets are indicative of absolute iron deficiency. A functional iron deficiency may exist when ferritin is greater than 500 ng/mL, TSAT is less than 20%, and anemia persists despite appropriate ESA therapy. In these cases, iron supplementation may lead to improved erythropoiesis. Other tests, including the percentage of hypochromic RBCs, reticulocyte hemoglobin content, serum transferrin receptor, RBC ferritin, and zinc protoporphyrin, have been proposed as indicators of iron status.[93] Although some of these markers have demonstrated predictive value in assessing iron status, either alone or in conjunction with other laboratory data, further investigation is warranted to determine their utility and to make such testing procedures readily available.

The availability of recombinant human EPO to directly stimulate erythrocyte production revolutionized the treatment of CKD-associated anemia. However, iron deficiency is the leading cause of ESA hyporesponsiveness and must be corrected before ESA therapy is initiated. Iron deficiency can develop as a result of increased requirements for RBC production with ESA administration and from chronic blood loss owing to bleeding or HD. Identification and management of iron deficiency through regular follow-up testing and iron supplementation is essential for adequate RBC production (see Case 28-1, Question 12, for Iron Therapy, and also Chapter 92, Anemias).[93]

Other factors that contribute to anemia include a shortened RBC life span secondary to uremia, blood loss from frequent phlebotomy and HD, GI bleeding, severe hyperparathyroidism, protein malnutrition, aluminum accumulation, severe infections, and inflammatory conditions.[93] Substances present in the plasma of patients with CKD, collectively termed uremic toxins, may inhibit the production of EPO, the bone marrow response to EPO, and the synthesis of heme. The negative effects of these substances on RBC production are supported by improvement in erythropoiesis with dialysis, which removes these uremic toxins. This uremic environment also causes a decrease in the RBC life span, from a normal life span of 120 days to approximately 60 days in patients with severe CKD. A shortened RBC life span has been observed in uremic patients transfused with RBCs from individuals with normal kidney function, whereas RBCs from uremic individuals maintain a normal survival time when transfused into patients without kidney failure.

Blood loss also contributes to anemia of CKD, particularly in patients requiring HD. With each HD session, generally performed 3 times a week, blood loss occurs. In addition, these patients are usually administered heparin during dialysis or antiplatelet drugs to prevent vascular access clotting, which further increases the risk of bleeding. Although a stool guaiac test was not performed in G.B., many patients with uremia and CKD will have a positive guaiac reaction because of the risk of bleeding from uremia itself. G.B. also has a peptic ulcer, which increases her potential for blood loss.

Other deficiencies can contribute to anemia of CKD. Deficiency of folic acid, as evidenced by low serum folate concentrations and macrocytosis, is relatively uncommon in patients with early kidney disease, but occurs most often in patients on dialysis because folic acid is removed by dialysis. Therefore, the daily prophylactic administration of the water-soluble vitamins, including 1 mg of folic acid, is recommended. Routine use of fat-soluble vitamin A is discouraged, because hypervitaminosis A may develop, contributing to anemia.[93] Several multivitamin preparations devoid of vitamin A (e.g., Nephrocaps) are available for patients with kidney failure. Pyridoxine (vitamin B_6) deficiency can also occur in both dialyzed and nondialyzed patients with CKD. Significant similarities are seen between this deficiency and the symptoms of uremia, which include skin hyperpigmentation and peripheral neuropathy. Current multivitamin products for patients with CKD 5D contain adequate amounts of pyridoxine to prevent deficiency.

Goals of Therapy

CASE 28-1, QUESTION 11: What are the goals of therapy for anemia of CKD in G.B.?

TARGET HEMOGLOBIN

Normalization of hemoglobin (i.e., ≥13 g/dL) in CKD should be avoided. In early 2007, an FDA-mandated black box warning was added to the safety labeling for all ESA products, which states that use of ESA therapy may increase the risk for death and for serious cardiovascular events when administered to achieve a hemoglobin greater than 12 g/dL. This came as a result of four completed cancer trials that evaluated new dosing regimens, use of ESA in a new patient population, and use of new unapproved ESA. Three trials have evaluated the efficacy and safety of hemoglobin targets in patients with CKD not on HD. In each study, the higher target hemoglobin groups (hemoglobin ≥13 g/dL) experienced increased cardiovascular events, stroke, or mortality rates; thus, observing these black box warnings in CKD is warranted.[96–98] Partial correction of anemia to approximately 11 g/dL is considered to offer improvements in quality of life, reduction in hospitalizations, and improvement in LVH.[99–101] It is at these targets that benefits such as increased survival, exercise capacity, quality of life, cardiac output, cognitive function, and decreased risk of LVH were observed in the CKD population. The KDIGO Clinical Practice Guideline for Anemia in Chronic Kidney Disease recommends a target hemoglobin of up to 11.5 g/dL.[93] Furthermore, for non-dialysis CKD patients with a hemoglobin <10.0 g/dL, the decision to start ESA therapy is based on the rate of fall of the hemoglobin.

Hemoglobin, rather than hematocrit, should be used to evaluate anemia in this population for several reasons. Hematocrit is dependent on volume status, which can be problematic for patients with fluctuations in plasma water (e.g., dialysis, volume overload). In addition, a number of variables can affect the hematocrit value including temperature, hyperglycemia, the size of the RBC, and the counters used for the test. These variables do not significantly affect hemoglobin, making it the preferred test for anemia.[93]

G.B.'s iron status should be evaluated first, and corrected if necessary. If achieving an adequate iron status does not improve anemia management, ESA therapy may be started (see Treatment section, and also Chapter 92, Anemias).

Treatment

CASE 28-1, QUESTION 12: Describe the options available to treat anemia of CKD and achieve the goals of therapy in G.B.

IRON THERAPY

Before initiating ESA therapy, G.B.'s iron indices should be determined. If G.B. is iron deficient, as indicated by the TSAT and serum ferritin and other supporting laboratory data (see Chapter 92, Anemias), supplemental iron therapy should be administered. If iron deficiency is the cause of anemia, G.B. may benefit from iron supplementation alone (i.e., without erythropoietic therapy) to increase hemoglobin. Peptic ulcer disease will need to be evaluated as a source of blood loss. Given the poor bioavailability of oral iron and patient noncompliance, oral iron is usually inadequate for repletion of iron in patients receiving HD who experience chronic blood loss.[102] For the population with early CKD and for patients receiving PD, an initial trial of oral iron may correct the deficiency because these patients do not have the same degree of blood loss. However, IV therapy will be required to replenish iron and meet the increased demands once erythropoiesis is stimulated with ESA therapy. Administration of IV iron requires IV access and frequent outpatient visits, which are drawbacks to therapy with IV iron in CKD 3 and 4. A trial examined an accelerated dosing regimen (500 mg given on two consecutive days) of IV iron sucrose to address these issues. This regimen was adequate to restore iron stores with only two patients experiencing hypotension related to iron therapy.[103] However, IV iron sucrose given 200 mg every 2 weeks for a total 1 g repletion in CKD 3 and 4 was associated with increased risk of cardiovascular causes and infectious diseases compared to oral ferrous sulfate.[104]

Common infusion-related effects associated with IV iron include hypotension, myalgias, and arthralgias. Despite the controversy about the best strategy for iron supplementation in patients with early CKD, current recommendations support reserving IV iron for patients in whom oral iron has failed.[93] Therefore, a trial of oral iron is reasonable for G.B. Oral iron supplementation with 200 mg/day of elemental iron should be started to address iron deficiency, if present, and this regimen should be continued to maintain sufficient iron status while receiving ESA therapy. Many oral iron preparations are available, and their iron content varies as will the number of tablets or capsules that must be taken per day to provide the required elemental iron (Table 28-8). Some oral formulations include ascorbic acid to enhance iron absorption. A heme iron product, Proferrin-ES, has recently been approved. Heme iron is more readily absorbed; however, a large number of tablets are required to supply the required 200 mg of elemental iron (Table 28-8). G.B. should be advised to take oral iron on an empty stomach to maximize absorption, unless side effects prevent this strategy. She also should be counseled on potential drug interactions with oral iron (e.g., antacids, quinolones) and GI side effects (e.g., nausea, abdominal pain, diarrhea, constipation, dark stools). Noncompliance with therapy as a result of side effects is a common cause of therapeutic failure with oral iron. An acidic environment is needed for adequate iron absorption, and acid-suppression therapies (e.g., proton-pump inhibitors) may limit the absorption of oral iron. Oral iron is a mucosal toxin, and her previous history of peptic ulcer disease requires caution with the use of oral iron.

Table 28-8

Oral Iron Preparations

Preparation	Common Brand Names	Commonly Prescribed Unit Size (Amount Elemental Iron in mg)[a]	Number of Units/Day to Yield 200 mg Elemental Iron
Ferrous sulfate	Slow FE, Fer-In-Sol	325 (65)	3 tablets
Ferrous gluconate	Feratab	325 (36)	5 tablets
Ferrous fumarate	Femiron, Feostat	200 (66)	3 capsules
Iron polysaccharide	Niferex, Nu-Iron	150 (150)	2 capsules
Heme iron polypeptide	Proferrin-ES	12 (12)	17 tablets
Carbonyl Iron	Fesol	45 (45)	4 tablets

[a] Unit size reflects common tablet or capsule sizes prescribed and not necessarily that of the brand names listed.

If G.B.'s condition does not respond to oral therapy, as indicated by either persistent iron deficiency based on iron indices or inadequate response to what is considered an adequate dose and duration of erythropoietic therapy, IV iron is necessary. The IV iron preparations currently available are iron dextran (INFeD, DexFerrum), sodium ferric gluconate complex in sucrose (Ferrlecit), iron sucrose (Venofer), ferumoxytol (Feraheme), and ferric carboxymaltose (Injectafer). Additionally, soluble ferric pyrophosphate citrate was approved by the FDA in 2015; this iron product is added to the dialysate used for hemodialysis. The dextran products have caused anaphylactic reactions and, as a result, have an FDA-mandated black box warning that requires administration of a 25-mg test dose followed by a 1-hour observation period before the total dose of iron is infused.[105] The dextran component is believed to be the cause of such reactions. The dose of IV iron recommended to correct absolute iron deficiency is a total dose of 1 g administered in divided doses or for a prolonged period to minimize the risk of adverse effects.[93] For iron dextran, the approved dose is 100-mg increments, administered during 10 dialysis sessions for patients on HD to provide a total of 1 g. Larger doses of 500 mg up to the total 1-g dose have been safely administered during a longer infusion period of 4 to 6 hours.

Sodium ferric gluconate and iron sucrose are the most widely used iron products in the CKD population. Both the ferric gluconate and iron sucrose products have been used successfully in patients who have experienced allergic reactions to the dextran products, and evidence indicates that they are safer: 8.7 adverse events per million doses for dextran versus 3.3 adverse events for gluconate.[102] To provide the recommended total dose of 1 g, ferric gluconate is administered as 125 mg (10 mL) during eight consecutive dialysis sessions for patients on HD. The dose can be administered as a slow IV injection at a rate of up to 12.5 mg/minute or diluted in 100 mL of normal saline and infused for 1 hour. Administration of 125 mg for 10 minutes (without a test dose) was determined to be a safer alternative to dextran preparations in patients on HD and is an approved dosing strategy. Doses up to 250 mg for 1 hour have been administered safely.[106] The flexibility of administering larger doses of iron is an important factor in achieving efficiencies in the outpatient setting for patients with early CKD and those receiving PD.

Iron sucrose (Venofer) is a polynuclear iron hydroxide sucrose complex. The recommended dose of iron sucrose is 100 mg (5 mL) during 10 consecutive HD sessions to provide the total dose of 1 g.[106] The dose can be administered by a slow IV injection for 5 minutes or diluted in 100 mL of normal saline and infused for at least 15 minutes. As with sodium ferric gluconate, a test dose is not required. Iron sucrose doses of 250 to 300 mg have been safely administered for 1 hour and found to be as effective as sodium ferric gluconate administration in maintaining hemoglobin in patients receiving epoetin.[106] Furthermore, iron sucrose has demonstrated the lowest anaphylaxis at first exposure and during total iron repletion.[107]

Smaller doses of IV iron, in increments of 25 to 200 mg, can be administered on a weekly, every 2-week, or monthly basis to patients without absolute iron deficiency. These doses will sustain adequate iron stores, maintain target hemoglobin values, and potentially reduce the required dose of the erythropoietic agent.[106] This regimen is most convenient for patients on HD who have regular IV access and increased iron needs because of chronic blood loss. Maintenance iron therapy replaces these losses and minimizes the need for the more aggressive 1-g total doses of IV iron required for absolute iron deficiency. If G.B. starts on HD in the future, regular dosing of IV iron during dialysis is the most reasonable way to maintain adequate iron required for sustained erythropoiesis. Iron indices should be monitored at least every 3 months to guide IV iron therapy. This strategy, however, could lead to increased exposure to free iron, which may place the patient at an increased risk of adverse effects (e.g., inflammation, oxidative stress).[108]

Ferumoxytol (Feraheme) is a semisynthetic carbohydrate-coated, superparamagnetic iron oxide nanoparticle approved for the treatment of iron deficiency anemia of CKD. The small content of free iron in the formulation allows for doses of 510 mg to be administered safely for 17 seconds, followed by a second 510-mg IV injection 3 to 8 days later. Contrary to previous IV iron formulations, a 1-g repletion regimen of ferumoxytol can be completed in two settings. Prospective, randomized studies in patients with CKD (categories 1–5) demonstrated the effectiveness of ferumoxytol in increasing hemoglobin levels in CKD patients compared with oral iron.[109] Ferumoxytol presents the same side effect profile as other IV iron preparations (i.e., hypotension or hypersensitivity reactions, including anaphylaxis or anaphylactoid reactions). The carbohydrate coating of ferumoxytol is suggested to reduce immunologic sensitivity, potentially resulting in less risk for anaphylactic type reactions compared with the other available high molecular weight IV iron products (e.g., iron dextran).[110] However, ferumoxytol has an adverse drug event rate of approximately 0.2% and the FDA has added a black box warning stating concern for fatal and serious hypersensitivity reactions particularly with the first dose.[111,112] Additionally, ferumoxytol can affect the diagnostic ability of magnetic resonance imaging for up to 3 months after the last dose.[111]

ERYTHROPOIESIS-STIMULATING AGENT THERAPY

Recombinant human EPO should be initiated for anemia of CKD in G.B. if there is no response in her hemoglobin to IV iron. Regular dialysis may improve an anemic condition, but it will not restore the hemoglobin concentrations to normal because the primary cause of anemia is reduced EPO production by the kidneys. Although blood transfusions were once the mainstay of treatment, they are now avoided, if possible, because they are associated with a risk for viral diseases (hepatitis, human immunodeficiency virus), iron overload, and further suppression of erythropoiesis. Transfusions may be required in certain patients with substantially low oxygen-carrying capacity or substantial blood loss, and in those patients exhibiting persistent symptoms of anemia (e.g., fatigue, dyspnea on exertion, tachycardia). Currently, G.B. is not a candidate for transfusions based on her hemoglobin of 9.3 g/dL and the absence of significant symptoms on presentation. Androgens raise EPO concentrations and were previously used to treat the anemia of CKD. However, inconsistent erythropoietic response, many adverse effects, and the availability of recombinant EPO have terminated the use of androgens as a treatment of anemia.

Human Erythropoetin-Epoetin Alfa

Human EPO or epoetin, the exogenous form of EPO, is produced using recombinant technology. Epoetin alfa is available in the United States, whereas epoetin beta is available primarily outside the United States. Since it became available in 1989, epoetin alfa (Epogen, Procrit) has provided an effective treatment option for anemia and has substantially decreased the need for RBC transfusions. Epoetin alfa stimulates the proliferation and differentiation of erythroid progenitor cells, increases hemoglobin synthesis, and accelerates the release of reticulocytes from the bone marrow.

For patients such as G.B. who do not yet require dialysis and for patients receiving PD, epoetin alfa is generally administered by subcutaneous (SC) injection. However, HD patients often receive epoetin alfa by IV administration because easy IV access is established. SC administration is preferred because lower doses can be administered less frequently and cost is lower than with IV administration. Starting doses for epoetin alfa administration are 50 to 100 units/kg 2 times weekly.[113] For patients being converted from IV to SC administration (half-life of epoetin alfa is 8.5 hours IV vs. 24.4 hours SC) whose hemoglobin is within the target range, the SC dose is usually two-thirds the IV dose. For patients not yet at the target hemoglobin, an SC dose equivalent to the IV dose is recommended. Patients receiving epoetin alfa SC should be instructed on the appropriate administration technique, which includes rotating the sites for injection (e.g., upper arm, thigh, and abdomen).

Darbepoetin Alfa

Darbepoetin alfa (Aranesp) was approved in 2001 for the treatment of anemia of CKD, regardless of dialysis requirements. Darbepoetin is a hyperglycosylated analog of epoetin alfa that stimulates erythropoiesis by the same mechanism. Instead of the three N-linked carbohydrate chains on epoetin alfa, darbepoetin has five, which increase the capacity for sialic acid residue binding on the protein. The increased protein binding slows total body clearance and increases the terminal half-life to 25.3 hours and 48.8 hours after IV and SC administration, respectively. Darbepoetin alfa’s longer half-life relative to epoetin alfa offers the potential advantage of less frequent dosing to maintain target hemoglobin values.

Studies in patients with CKD 3 and 4 determined that starting SC doses of 0.45 mcg/kg administered once per week and 0.75 mcg/kg once every other week were effective in achieving target hemoglobin and hematocrit values in patients who had not previously received erythropoietic therapy.[114] In patients on dialysis converted from epoetin alfa to darbepoetin alfa (IV and SC), darbepoetin maintained target hemoglobin values when administered less frequently (i.e., one dose every week in patients previously receiving epoetin alfa 3 times/week, and one dose every other week in patients previously receiving epoetin once weekly).

The approved starting dose of darbepoetin alfa in patients who have not previously received epoetin therapy is 0.45 mcg/kg given either IV or SC once weekly.[115] Patients who are already receiving epoetin therapy may be converted to darbepoetin alfa based on the current total weekly epoetin dose (Table 28-9).[115] For patients currently receiving epoetin alfa 2 to 3 times a week, darbepoetin alfa may be administered once weekly. Patients who are receiving epoetin alfa once weekly should receive darbepoetin alfa once every 2 weeks. To calculate the once every 2-week darbepoetin dose, the weekly epoetin alfa dose should be multiplied by 2 and that value used in column 1 of Table 28-9 to find the corresponding darbepoetin dose from column 2 in Table 28-9. For example, a patient receiving epoetin 6,000 units/week should receive 40 mcg of darbepoetin alfa once every 2 weeks (6,000 units epoetin × 2 = 12,000 units, which corresponds to a weekly darbepoetin dose of 40 mcg).[115]

Epoetin alfa and darbepoetin alfa are generally well tolerated, with hypertension being the most common adverse event reported. Although elevated BP is not uniformly considered a contraindication to therapy, BP should be monitored closely so that changes in antihypertensive therapy and the dialysis prescription are made, if justified. Failure to elicit a response to erythropoietic therapy requires evaluation of factors that cause resistance, such as iron deficiency, infection, inflammation, chronic blood loss, aluminum toxicity, malnutrition, and hyperparathyroidism. Resistance to erythropoietic therapy has been observed in patients receiving ACEI, although data are conflicting.[116] Rare cases of antibody formation to epoetin therapy have been reported primarily with one epoetin alfa product manufactured outside the United States. Neutralizing anti-EPO antibodies were identified in 13 patients with pure RBC aplasia who required blood transfusions after a course of therapy with epoetin alfa or beta.[117]

Treatment of G.B.'s anemia must be initiated, given the chronic nature of her kidney disease and her current hemoglobin. In patients with hemoglobin values less than 10 g/dL, it is important to identify and correct any iron or folate deficiency and perform a stool guaiac test to rule out active GI bleeding. Iron supplementation is indicated, not only if G.B. is iron deficient but also to maintain iron status while receiving erythropoietic therapy (see Iron Therapy section). Although administration of iron alone may improve her anemia, epoetin alfa or darbepoetin alfa may likely be required, based on the severity of her anemia and the progressive nature of her kidney disease. G.B. may start darbepoetin alfa administered at a dose of 25 mcg (0.45 mcg/kg) SC once per week, assuming her iron status is appropriate (see Iron Status section). Another option would be epoetin alfa at a dose of 6,000 units (approximately100 units/kg) administered SC once per week or divided into two weekly doses of 3,000 units. She also should be instructed on how to administer SC epoetin alfa or darbepoetin alfa. Dose adjustments should not be made more frequently than once every 4 weeks for either agent because of the time course for response (i.e., the pharmacodynamic effects on RBC homeostasis). The time it takes to reach a new steady state, when RBC production is equal to RBC destruction, depends on the life span of the RBC, which is approximately 60 days in patients with kidney failure. Therefore, it will take approximately 2 to 3 months to reach a plateau in measured hemoglobin. Dose adjustments should be made on the basis of G.B.'s hemoglobin, which should be monitored every 1 to 2 weeks after initiation of therapy or after a dose change. If a rapid increase in hemoglobin is observed (hemoglobin >1.0 g/dL during any 2-week period) or approaching 11.5 g/dL, then doses of either agent should be decreased by approximately 25%. If response is inadequate (hemoglobin increase <1 g/dL in 2–4 weeks), then the doses should be increased by 25%. Once stable, the hemoglobin should be monitored every 2 to 4 weeks. If a response is not observed despite appropriate dose titration, G.B. should be evaluated for possible reasons for nonresponse (i.e., iron deficiency, bleeding, aluminum intoxication, hyperparathyroidism, infection).

Table 28-9

Estimated Darbepoetin Alfa Starting Doses Based on Previous Epoetin Alfa Dose

Previous Weekly Epoetin Alfa Dosage (units/week)	Weekly Starting Darbepoetin Alfa Dosage (mcg/week)	
	Adults	**Children**
<1,500	6.25	[a]
1,500–2,499	6.25	6.25
2,500–4,999	12.5	10
5,000–10,999	25	20
11,000–17,999	40	40
18,000–33,999	60	60
34,000–89,999	100	100
≥90,000	20	200

[a] For children receiving a weekly epoetin alfa dosage of <1,500 units/week, the available data are insufficient to determine a darbepoetin alfa conversion dosage.

Other ESA Agents

The ESA peginesatide, a pegylated peptide, was FDA approved for anemia treatment in dialysis patients in March 2012. However, peginesatide was withdrawn from the market by the manufacturer after serious hypersensitivity reactions, including anaphylaxis, were reported.

Continuous EPO receptor activator (Mircera) is a long-acting ESA. CERA is twice the molecular weight of EPO from the addition of a single 30-kDa polymer chain into the EPO molecule that results in a considerably longer elimination half-life compared with EPO (130 hours vs. 4–28 hours). This allows for extended-interval dosing of biweekly and once monthly. It has an efficacy and safety profile comparable to other available ESAs. Extended-interval dosing agents, such as CERA, have several advantages in patients with CKD 3 and 4, including improved patient compliance, less administration costs, reduced burden on patient from fewer injections given, and fewer outpatient visits to receive IV administration.[118]

CARDIOVASCULAR COMPLICATIONS

CASE 28-2

QUESTION 1: H.B. is a 65-year-old white man with category 5 CKD who has just started chronic HD. He comes in today for his third HD session (dialysis scheduled 3 times/week, 4-hour duration). He has a history of hypertension, which has been poorly controlled during the past 4 months (BP ranges 150–190/85–105 mm Hg), and has experienced shortness of breath and a significant weight gain during the past month. His pertinent medical history includes hypertension for the past 14 years. H.B.'s current medications include metoprolol tartrate 50 mg BID, furosemide 80 mg BID, calcium carbonate 500 mg TID with meals, and Nephrocaps one by mouth (PO) every day. H.B.'s most recent predialysis BP was 195/100 mm Hg, and his postdialysis BP was 168/90 mm Hg. A recent ECG showed evidence of LVH.

Predialysis laboratory values were as follows:

Serum sodium (Na)	140 mEq/L
Potassium (K)	5.1 mEq/L
Chloride (Cl)	101 mEq/L
CO_2 content	23 mEq/L
SCr	8.8 mg/dL
BUN	84 mg/dL
Phosphate	6.5 mg/dL
Calcium	8.6 mg/dL
Serum albumin	3.0 g/dL
Cholesterol (nonfasting)	345 mg/dL
Triglycerides	285 mg/dL
TSAT	18%
Ferritin	250 ng/mL
Hct	27%
Hgb	9.0 g/dL

H.B. has a urine output of 50 mL/day. What conditions evident in H.B. place him at increased risk of cardiovascular complications and mortality?

H.B. has uncontrolled hypertension that is not adequately managed with his current drug therapy or HD. Hypertension is associated with LVH, ischemic heart disease, and heart failure, all of which are contributing factors to overall mortality in patients with CKD 5D who are undergoing dialysis.[4] H.B.'s ECG evidence of LVH should trigger additional evaluation to determine the extent of cardiac involvement and diagnosis of heart failure, which is associated with increased mortality in both diabetic and nondiabetic patients (see Chapter 14, Heart Failure).[95] LVH develops early in the course of CKD and progresses as kidney disease progresses. H.B. is in the most severe stage of CKD and has the greatest likelihood of developing LVH. Anemia contributes substantially to the development of LVH and heart failure as well. H.B.'s hemoglobin of 9.0 g/dL is below the target value and requires treatment based on evaluation of his iron indices (see Anemia section).

Additional factors that increase the risk of cardiovascular complications and mortality in H.B. include elevated cholesterol and triglycerides levels as well as hypoalbuminemia (serum albumin, 3.0 g/dL). Increased levels of homocysteine are common in patients with kidney failure and have been associated with increased risk of coronary artery disease.[119] Because elevated concentrations of homocysteine have been observed in conjunction with decreased folate and vitamin B_{12} levels, more aggressive supplementation of these vitamins in this population has been suggested. Because H.B.'s total corrected calcium (corrected for hypoalbuminemia; see Case 28-3, Question 2, for an explanation of this correction) is 9.4 mg/dL, his calcium and use of a calcium-containing phosphate binder will need to be monitored frequently.

Cardiac calcification is common in patients with kidney disease and also is associated with cardiovascular complications. It has been reported that approximately 80% of patients with ESRD have detectable coronary artery calcification.[120] CVD and complications continue to be the leading cause of mortality in patients with kidney failure.[1]

Hypertension

CASE 28-2, QUESTION 2: What options are available to treat H.B.'s hypertension considering his other cardiac complications and BP goal?

DIALYSIS

Hypertension is common in patients with CKD. Multiple factors are involved in the development of hypertension in the CKD population, including extracellular volume expansion from salt and water retention and activation of the renin–angiotensin–aldosterone system.[116] Additionally, the increase in uremic toxins leads to sympathetic nervous system stimulation and elevation of BP.[121]

Because H.B. is just beginning dialysis therapy, it is difficult to assess the degree to which volume removal will ultimately affect his BP. To control BP related to volume changes, dialysis therapy should be adjusted as needed to achieve H.B.'s dry weight, the postdialysis weight at which symptoms of hypervolemia and hypovolemia are absent (i.e., normovolemia and free from edema). H.B. has had recent findings consistent with worsening volume status (shortness of breath, weight gain) that should be considered when modifying his dialysis prescription; further workup is needed to determine whether H.B. has systolic or diastolic heart failure. It is also important to counsel H.B. on the importance of salt and fluid intake restriction between HD sessions to minimize weight gain, volume expansion, and hypertension. Restriction of salt

---

intake to less than 2.4 g/day and fluid to 1 L/day is appropriate and will require regular follow-up by a dietitian.

ANTIHYPERTENSIVE THERAPY

Currently, there are no published guidelines for the management of hypertension in patients receiving hemodialysis. Although there are no published guidelines, control and management of hypertension is important. Antihypertensive therapy should be used in conjunction with dialysis therapy in H.B. to a target BP. In the absence of published guidelines targeting a BP of <150/90 mm Hg before HD is reasonable.

For some patients, initiation of dialysis alone may achieve this goal, and antihypertensive therapy may be withdrawn. The aim of the BP goal in patients with CKD 5D is to minimize cardiovascular complications, but it should not increase the risk for hypotension and its associated complications during dialysis. The choice of an agent is based on the patient's comorbid conditions because no single agent has a consistently proven mortality benefit in patients on HD. The complexity of managing hypertension in patients on HD is enhanced by the apparent U-shaped relationship between BP and mortality.[122] A study of patients on HD found an increased risk of cardiac-related death at a systolic BP less than 110 mm Hg and at a systolic BP greater than 180 mm Hg.[123] Another cohort study found a systolic BP between 100 and 125 mm Hg was associated with the lowest risk of death, and systolic BP >150 mm Hg associated with increased death.[122] The mortality risk with a low pre-HD BP may be indicative of severe cardiac disease at the initiation of HD. If patients experience hypotensive symptoms during HD, the goal BP can be increased, but they also should be evaluated for other cardiovascular disorders. Because the BP between dialysis sessions varies owing to volume changes, the ideal time to measure BP relative to dialysis (i.e., predialysis versus postdialysis) is unclear, but predialysis BP has been favored.

Diuretics are commonly used in patients in the early stages of CKD. As discussed previously, the effectiveness of diuretics depends on the amount of sodium delivered to their site of action in the kidney tubule and on the patient's kidney function. For example, a decrease in the eGFR from 125 to 25 mL/minute/1.73 m^2, theoretically, could result in an approximate 80% decrease in the amount of sodium filtered. Early in the course of kidney failure, thiazides or thiazide-like diuretics are effective antihypertensive agents. As eGFR is further reduced (eGFR <30 mL/minute/1.73 m^2), the thiazide diuretics become less effective. Potassium-sparing diuretics are also ineffective and may increase the risk of hyperkalemia. Loop diuretics (e.g., furosemide), which function more proximally, are indicated in patients with CKD 4 (eGFR 15–29 mL/minute/1.73 m^2).[124] These drugs can be effective for BP and volume control in patients with advanced kidney disease if residual kidney function is substantial (urine output >100 mL/day). Their effect must be frequently reevaluated on the basis of urine output and any effect on volume control. H.B.'s urine output should be assessed to determine the rationale for continued use of furosemide, and the current dose should be assessed because doses higher than his current dose of 80 mg BID are often required in patients with this degree of kidney dysfunction. It is likely that furosemide will need to be discontinued as H.B.'s residual kidney function declines.

Given the role of the renin–angiotensin system in the development of hypertension in patients with CKD, ACEIs are a logical choice for antihypertensive therapy. ACEIs are effective antihypertensive agents in patients with CKD and have been shown to reverse LVH.[125] ACEIs are underused in this population. Response must be assessed individually to determine whether renin–angiotensin–aldosterone activity is a predominant etiology of hypertension. Initiating therapy with low doses is prudent to evaluate patient response and tolerance. Use of these agents in combination with other antihypertensives is often required for adequate BP control. Most of these agents can be administered once daily; however, because of the kidney elimination of the parent drug or active metabolite, dosage adjustments are necessary in patients with CKD. ACEI use should be avoided in patients undergoing dialysis with the polyacrylonitrile (AN69) membranes. The AN69 dialyzer increases bradykinin production, whereas ACEIs decrease the breakdown of bradykinin, predisposing patients to systemic or immune-mediated reactions that can lead to anaphylactic reactions.

ARBs effectively lower BP and reverse LVH in patients without kidney disease.[126] These agents offer an alternative to ACEIs in patients experiencing kinin-mediated adverse effects; however, similar side effects have been reported with ARBs.

β-Adrenergic blockers (β-blockers) inhibit release of renin and may be useful in hypertension associated with CKD. β-Blockers can counteract the elevated sympathetic activity observed in dialysis patients, lower the risk of sudden cardiac death, and improve survival in heart failure.[127] Unfortunately, they are underutilized, and the mentioned benefits are understudied in the dialysis population.[128] Risk versus benefit should be evaluated when β-blockade is considered in conjunction with other comorbid conditions such as asthma, heart failure, and lipid abnormalities. Dosage adjustment is required for the less lipophilic agents (i.e., atenolol, nadolol).

Calcium-channel blockers are effective antihypertensive agents in patients with CKD. Because the nondihydropyridine agents (i.e., diltiazem, verapamil) have negative chronotropic and inotropic effects, they should be used with care in patients with heart disease. Generally, dosage adjustment is not required in patients with kidney disease.

Other agents used to treat hypertension in the CKD population include centrally acting agents (e.g., clonidine, methyldopa), vasodilators (e.g., minoxidil, hydralazine), and α_1-adrenergic blockers (prazosin, terazosin, doxazosin). However, these agents are generally reserved as last-line therapies.

H.B. is currently taking the β-blocker metoprolol and the loop diuretic furosemide. Metoprolol is a β-blocker considered to be removed by dialysis and should be monitored closely for H.B. clinical response to the therapy while starting dialysis. It is likely that his diuretic will need to be discontinued as his residual kidney function decreases and response to therapy is inadequate. If changes imposed in H.B.'s HD prescription are able to improve volume control and achieve his dry weight but do not reduce his BP, another antihypertensive regimen should be selected. A reasonable antihypertensive regimen would include an ACEI (e.g., ramipril). The selection will depend substantially on follow-up results of his cardiac disease, BP control with HD, and the development of adverse effects (see Chapter 9, Essential Hypertension, and Chapter 14, Heart Failure).

Dyslipidemia

CASE 28-2, QUESTION 3: How should H.B.'s lipid abnormalities be treated?

H.B. has elevated serum cholesterol and triglyceride concentrations, a common finding in patients with CKD. Dyslipidemia and increased oxidative stress contribute to premature atherogenesis in these patients. Several atherogenic factors in patients with CKD have been postulated, including arterial wall injury, platelet activation and adherence, smooth muscle cell proliferation, and intraarterial accumulation of cholesterol. Lowering of serum lipids has not been shown to improve morbidity and mortality in hemodialysis patients. Furthermore, current KDIGO Guidelines for Lipid Management in CKD do not recommend using cholesterol values to determine who to treat or as treatment targets. Currently, H.B. is not receiving a statin which has not demonstrated the ability to reduce mortality or morbidity in dialysis. If concern with treating H.B.'s dyslipidemia persists, a moderate-intensity statin may be considered. Dietary intervention successfully reduces triglyceride and cholesterol concentrations in patients with CKD 5D.

MINERAL AND BONE DISORDERS

CASE 28-3

QUESTION 1: W.K. is a 24-year-old Hispanic woman who has an 18-year history of type 1 diabetes mellitus with complications of diabetic nephropathy, retinopathy, and neuropathy. She was diagnosed with CKD 5 two years ago. She started PD at that time. Her current medications include metoclopramide (Reglan) 10 mg TID before meals, insulin aspart 10 units with meals, insulin glargine 25 units nightly, docusate 100 mg every day, calcium acetate 2001 mg PO TID with meals, EPO 5,000 units IV twice weekly, iron sucrose 100 mg IV 3 times a week, paricalcitol 4 mcg IV 3 times weekly, and Nephrocaps one capsule every day. At a recent clinic visit, findings on physical examination included a BP of 128/84 mm Hg, diabetic retinopathic changes with laser scars bilaterally, and diminished sensation bilaterally below the knees. Her laboratory values were as follows:

Normal serum electrolytes
Random blood glucose, 250 mg/dL
BUN, 45 mg/dL
SCr, 8.9 mg/dL
Hgb, 10 g/dL
WBC count, 6,200/μL
Calcium, 10.2 mg/dL
Phosphate, 6.8 mg/dL
Intact parathyroid hormone (iPTH), 950 pg/mL
Thyroid-stimulating hormone, 5 mIU/L
Total serum protein, 5.0 g/dL

Serum albumin, 3.1 g/dL

Uric acid, 8.9 mg/dL

Describe the etiology of W.K.'s abnormal bone, calcium, phosphorus, and parathyroid hormone (PTH) findings.

Etiology

MND of CKD (CKD-MBD) is the term used to collectively describe the mineral (e.g., phosphorus, calcium, PTH), bone (osteodystrophy), and soft-tissue calcification abnormalities that develop as a complication of CKD. The older collective term of renal osteodystrophy failed to adequately illustrate the broader clinical complications associated with the biomarker abnormalities and calcification, and is now only used to describe, specifically, the bone pathology.[92]

Hyperphosphatemia, hypocalcemia, hyperparathyroidism, decreased production of active vitamin D, and resistance to vitamin D therapy are all frequent problems in CKD that can lead to the secondary complications of CKD-MBD. Although the interrelationships among phosphorus, calcium, vitamin D, and PTH have been reviewed extensively, fibroblast growth factor 23 (FGF23), a phosphaturic hormone, has added some new insight.[129] Increased dietary phosphorus intake stimulates FGF23 secretion. FGF23 increases phosphorus excretion via the proximal tubules, inhibits vitamin D activation, increases activated vitamin D catabolism, and is associated with kidney disease progression.[130]

At a GFR above 30 mL/minute/1.73 m^2, elevations in FGF23 and PTH maintain normal serum phosphorus. This concept is referred to as the trade-off hypothesis, where the ability to maintain normal phosphorus concentrations occurs at the expense of developing secondary hyperparathyroidism (SHPT), the excessive secretion of PTH and elevated FGF23. However, FGF23 is not currently measured in the clinical setting. Clinically significant increases in serum phosphorus (or frank hyperphosphatemia) typically are not seen until late stages of CKD, GFR <30 mL/minute/1.73 m^2, when compensatory mechanisms within the kidney are compromised.

The kidney is the principal organ responsible for systemic vitamin D production, and, as such, vitamin D metabolism is altered in the presence of uremia. Persistent hyperphosphatemia stimulates the release of excessive FGF23, which inhibits the normal conversion of 25-hydroxyvitamin D_3 to its biologically active metabolite, 1,25-dihydroxyvitamin D_3, by the enzyme 1-α-hydroxylase (Fig. 28-2). This enzyme is present in proximal tubular cells of the kidney and is necessary for conversion of vitamin D to the active form. This active form of vitamin D, also known as calcitriol, increases gut absorption of calcium and interacts with vitamin D receptors on the parathyroid gland to suppress PTH release. As a result of decreased calcitriol production, the absorption of dietary calcium in the gut is diminished. Decreased suppression of PTH release by vitamin D in conjunction with hypocalcemia promotes continued stimulus for mobilization of calcium from bone. Furthermore, uremic patients require a higher extracellular calcium concentration to suppress secretion of PTH. This is also described as an increase in the calcium “set point” or the concentration of calcium required to inhibit 50% of maximal PTH secretion.[131]

The chronic effects of hyperparathyroidism on the skeleton lead to bone pain, fractures, and myopathy. In children, these effects may be particularly severe and usually retard growth. The metabolic acidosis of kidney disease also contributes to a negative calcium balance in the bone.

W.K.’s presentation is consistent with CKD-MBD based on the observed changes in bone architecture and abnormalities in serum phosphorus, calcium, and PTH; all can be attributed to her kidney disease.

Vitamin D levels (i.e., 25-hydroxyvitamin D) should be checked in CKD 3. Insufficient (<30 ng/mL) and deficient (<15 ng/mL) vitamin D levels are prevalent in the majority of CKD and ESRD patients. Several studies have linked depressed vitamin D levels to increased vascular calcification, CVD, and mortality.[132]

Treatment

CASE 28-3, QUESTION 2: What are the goals of therapy for W.K.'s calcium, phosphorus, and PTH abnormalities? What options are available to treat these disorders?

The management objectives for W.K. are to (a) manage serum calcium and phosphorus concentrations, (b) prevent or manage SHPT, and (c) restore normal skeletal development without inducing adynamic bone disease (or low bone turnover). These goals are best achieved with dietary phosphorus restriction, appropriate use of phosphate-binding agents, vitamin D therapy, calcimimetics, and dialysis.

DIETARY RESTRICTION OF PHOSPHORUS

In general, serum phosphorus should be lowered toward near-normal levels. The KDIGO recommends normal levels for all stages of CKD. Dietary phosphorus restriction can prevent hyperphosphatemia and maintain target phosphorus concentrations. Dietary phosphorus should not exceed 800 to 1,000 mg/day.[92] Predominate sources of phosphorus are protein-rich foods, which presents a challenge in tailoring a diet that lowers dietary phosphorus intake while providing adequate nutrition. However, efforts should be made to distinguish between organic (e.g., plant seeds, nuts, legumes, and meats) and inorganic phosphorus (e.g., preservatives and additive salts found in processed foods) sources. Inorganic phosphorus sources are absorbed to a greater extent than organic phosphorus (90% vs. 50%, respectively) and should be minimized in the diet.[133] Dark carbonated beverages are a common culprit for elevated phosphorus levels; their consumption should be discouraged, and the beverages should be removed from vending machines in dialysis clinics. Additionally, the type of organic phosphorus sources, plant versus meat, has varying effects with plant sources associated with lower serum phosphorus levels and decreased FGF23 levels. Although phosphorus is removed to some extent by dialysis, neither conventional HD nor PD removes adequate amounts to warrant complete liberalization of phosphorus in the diet. Nocturnal HD is an exception where patients may require phosphate supplements because of the prolonged dialysis duration. Regular dietary counseling by a kidney dietitian specialist is necessary to reinforce the importance of phosphorus restriction and other dietary recommendations.

PHOSPHATE-BINDING AGENTS

A significant reduction in serum phosphorus is difficult to achieve with dietary intervention alone, particularly in patients with more advanced kidney disease (eGFR <30 mL/minute/1.73 m^2). For these patients, phosphate-binding agents used in conjunction with dietary restriction are necessary. Phosphate-binding agents limit phosphorus absorption from the GI tract by binding with the phosphorus present from dietary sources. Therefore, these agents must be administered with meals. Available binders include products that contain calcium, iron, lanthanum, aluminum, or magnesium cations or the polymer-based agent, sevelamer.

Calcium-Containing Preparations

Calcium-containing preparations, especially calcium carbonate and calcium acetate, are frequently used to prevent hyperphosphatemia in patients with kidney disease. The many preparations available vary in their calcium content (Table 28-10). Correction of hypocalcemia is an added beneficial effect of the calcium-containing preparations; however, a risk exists of hypercalcemia and cardiac calcification associated with the prolonged use of these agents.[134] Additionally, the higher bioavailable calcium in calcium carbonate may lead to positive calcium balance.[135] Calcium citrate is a calcium salt with a phosphate-binding capacity similar to that of calcium carbonate; however, because it also increases aluminum absorption from the GI tract, its use is not recommended in patients with kidney disease.

Simultaneous administration of vitamin D preparations and calcium also increases the risk of hypercalcemia. A corrected serum calcium should be determined before therapy is started and at regular intervals thereafter.

Many clinicians often correct calcium levels for low albumin. Although this practice is still very common, new Medicare Quality Improvements will be based on uncorrected total serum calcium levels. Calculating corrected calcium adjusts for the change in the ratio of free (unbound) versus protein-bound calcium owing to reduced serum albumin concentrations (Eq. 28-7).

$$\text{Corrected calcium (mg/dL)} = \text{measured Ca (mg/dL)} + 0.8 \times (4\ \text{g/dL} - \text{measured albumin [g/dL]}) \qquad \text{(Eq. 28-7)}$$

Calcific uremic arteriolopathy (CUA) or calciphylaxis, is characterized by calcification of the arterioles and small arteries with intimal proliferation and endovascular fibrosis. CUA and manifests visually as necrosis of the skin and is most frequently seen in dialysis patients, affecting up to 5% of patients. Calcium-based phosphate binders are one of the triggering factors associated with the development of CUA.

If the patient experiences hypercalcemia or evidence of advance calcification, the patient should be switched to a non–calcium-based phosphate binder. Alternatives include sevelamer and cations, such as lanthanum carbonate or magnesium preparations. For patients requiring dialysis, reducing the calcium concentration of the dialysate bath may decrease the risk of hypercalcemia. Although avoiding hypercalcemia should reduce the risk of cardiac calcification, calcifications still can occur because of other contributing factors in the CKD population (e.g., hyperphosphatemia).

Nausea, diarrhea, and constipation are other side effects of calcium-containing products. Because calcium-containing phosphate binders may interact with other drugs, the timing of their administration relative to other agents must be considered. Fluoroquinolones and oral iron, for example, should be taken at least 1 or 2 hours before calcium-containing phosphate binders. Importantly, if the calcium products are being used as supplementation to treat hypocalcemia or osteoporosis, they should be taken between meals to enhance intestinal absorption. This is in contrast to their administration with meals if they are being used as phosphate binders. Starting doses of common calcium-containing phosphate binders are listed in Table 28-10.

Sevelamer

Sevelamer hydrochloride (Renagel) or carbonate (Renvela) is a nonabsorbed, polymer-based product that binds phosphorus in the GI tract.[136,137] The benefit of lowering phosphorus without significantly affecting serum calcium has led to the increased use of sevelamer in patients with CKD. Sevelamer also lowers LDL and total serum cholesterol, a benefit considering the increased risk of cardiovascular events in this population.[92]

Sevelamer has a potential benefit of attenuating the progression of coronary calcification, which may be related to its LDL and total serum cholesterol-lowering effects and a benefit from reduced calcium loading. The actual benefit of sevelamer on mortality is controversial. The post hoc analysis of the Renagel in New Dialysis (RIND) trial showed a survival advantage with sevelamer compared with calcium acetate; however, the Dialysis Clinical Outcomes Revisited (DCOR) trial failed to show a difference in mortality between the two agents.[138] One explanation for the disparity in results may be the difference in the population of patients on HD between the two trials. The RIND trial included incident patients on HD, whereas the DCOR trial included prevalent HD patients who likely would have advanced CVD.

Table 28-10

Available Phosphate Binders

Agent	Availability (Pill Burden)	Comments	Adverse Effects and Warnings
Aluminum-Based Binder			
Aluminum hydroxide	320 mg/5 mL suspension	OTC	Constipation and sodium overload Aluminum toxicity: CNS, anemia, and bone disease Warnings: perforation, fecal impaction, ileus
Calcium-Based Binders			
Calcium acetate	667 mg caplets (3–12 caplets) 667 mg/5 mL (15–20 mL with meal)	Oral solution associated with higher diarrhea risk	N/V/D; hypercalcemia; vascular calcification; oral solution associated with greater diarrhea
Calcium carbonate	500–1,250 mg tablets	OTC	N/V/D; hypercalcemia; vascular

	(3–6 tablets)		calcification
Iron-Based Agents			
Ferric citrate	210 mg ferric iron tablet (6–12 tablets)	210 mg of ferric iron = 1 g ferric citrate	N/V/D; discolored feces; iron overload Precautions: gastric/hepatic disorders; CI: hemochromatosis
Sucroferric oxyhydroxide	500 mg chewable tablet (3–6 tablets)	500 mg ferric iron = 2,500 mg sucroferric oxyhydroxide	N/D; discolored feces; iron overload Precautions: gastric/hepatic disorders; hemochromatosis
Lanthanum-Based Binder			
Lanthanum	500, 750, and 1,000 mg chewable tablets (3–6 tablets)	Chewed and crushed have similar efficacy	Accumulation in bone, brain, and liver; visible on abdominal X-ray; hypercalcemia CI: bowel obstruction, ileus, and fecal impaction
Magnesium-Based Binder			
Magnesium hydroxide	311 mg tablets (1–6 tablets)	OTC; impair iron absorption	Hypermagnesemia; diarrhea very common
Resin Binders			
Sevelamer carbonate	800 mg caplet (3–12 caplets) 0.8 g/2.4 g powder packets	Reduces low-density lipoprotein cholesterol	N/V/D; hypercalcemia CI: bowel obstruction Warnings: perforation, fecal impaction
Sevelamer hydrochloride	400, 800 mg caplets 1–2 tablets TID (6–12 caplets)	Reduces low-density lipoprotein cholesterol	N/V/D; hypercalcemia CI: bowel obstruction Warnings: perforation, fecal impaction; risk of metabolic acidosis

CI, contraindications; N/V/D, nausea, vomiting, diarrhea.

Sevelamer hydrochloride is available as 400- and 800-mg tablets. Sevelamer carbonate is available as 800-mg tablets and 0.8-g powder packets. The phosphorus-binding capacity remains equipotent between the two formulations. The starting dose is variable and depends on the baseline serum phosphorus concentration (800 mg TID with meals if serum phosphorus is <7.5 mg/dL; 1,600 mg TID with meals if serum phosphorus is >7.5 mg/dL).[136,137] Gradual adjustments can be made at 2-week intervals, based on serum phosphorus levels. Dosing guidelines for sevelamer are also available for patients being converted from calcium acetate. On the basis of studies showing similar reductions in serum phosphorus, 800 mg of sevelamer is considered equivalent to 667 mg of calcium acetate (169 mg of elemental calcium).[137]

The administration of sevelamer hydrochloride to patients on HD is associated with a lowering of serum bicarbonate; this effect should be taken into account when using this agent. Sevelamer carbonate avoids the metabolic acidosis seen with the hydrochloride formulation and raises the serum bicarbonate level.[139] Adverse reports of fecal impaction, ileus, intestinal obstruction, and perforation should caution the use in patients with GI disease. The current prescribing information recommends administering sevelamer 1 hour before or 3 hours after administration of other agents with narrow therapeutic indices.[136,137]

Lanthanum Carbonate

Lanthanum carbonate (Fosrenol) is a noncalcium, nonaluminum phosphate binder preparation. When ingested, it dissociates into a trivalent cation with similar binding capacity as aluminum salts. Lanthanum also has been found to be as effective and tolerable as standard treatment. Both calcium and iPTH were lower in the lanthanum group.[140] Lanthanum is mainly excreted via the biliary route, with minimal kidney elimination.

Studies have evaluated the deposition and toxicity of lanthanum in the bone, liver, and brain due to concerns of lanthanum accumulation. Although lanthanum accumulates in lysosomes in the liver, this has not been correlated with increased liver enzymes or hepatobiliary adverse events in patients receiving lanthanum for up to 6 years.[141] This is likely an excretory process through the biliary tract similar to that for iron and copper. A prospective trial of patients on HD receiving lanthanum for 1 year found minimal deposition of lanthanum within the bone and less likelihood of adynamic bone histology compared with patients receiving calcium carbonate.[142] During a 2-year period, patients receiving lanthanum were not found to accelerate the natural deterioration in cognitive function seen in patients on HD.[143]

Lanthanum is supplied as chewable tablets for oral administration in four strengths: 250, 500, 750, and 1,000 mg. The recommended initial total daily dose is 750 to 1,500 mg given with meals, and dosage titration up to a maximal dosage of 3,000 mg daily based on serum phosphate levels. Lanthanum retains the same phosphorus-binding capabilities irrespective of whether it is chewed or crushed into powder.[144] Drug interactions with lanthanum include a reduction in the bioavailability of ciprofloxacin (approximate 50% reduction) and levothyroxine. The most frequent adverse events reported in clinical trials are nausea and vomiting.[145]

Iron-Based Phosphate Binders

Sucroferric oxyhydroxide and ferric citrate are iron-based phosphate binders with proven efficacy at reducing serum phosphate levels in hemodialysis patients. The newer iron-based binder ferric citrate has the advantage of providing supplemental iron. Early studies of ferric citrate demonstrate a reduction in IV iron and EPO-stimulating agent use.[146] However, sucroferric oxyhydroxide as a chewable tablet is not systemically absorbed, thus not affecting anemia management.[147]

Other Phosphate Binders

Aluminum preparations are very potent dietary phosphorus binders. Although these products were once used as first-line agents to decrease phosphorus, aluminum accumulation and toxicities in patients with CKD have restricted their use. Aluminum toxicity occurs in dialysis patients because absorbed aluminum is not removed by the diseased kidney and enters various tissues where it binds to tissue and plasma proteins. Aluminum accumulation in the bone, brain, and other organs leads to toxicities such as osteomalacia (aluminum-related bone disease), microcytic anemia, and a fatal neurologic syndrome referred to as dialysis encephalopathy.[91] Treatment of aluminum toxicity requires chelation with deferoxamine. Aluminum-containing agents should only be considered on a short-term basis (up to 4 weeks) for patients with a severely elevated phosphorus[91]; however, high-dose lanthanum may generally be preferred in these situations. Sucralfate, used primarily for the treatment of ulcers, also contains aluminum and should be used cautiously in patients with kidney disease.

Magnesium agents (magnesium hydroxide, magnesium carbonate) may be beneficial, but as with aluminum, their use should be limited because at the high doses required to control serum phosphorus concentrations, severe diarrhea and hypermagnesemia invariably result. Magnesium may be considered in patients whose serum phosphorus concentrations cannot be controlled adequately by other phosphate-binding agents. In this instance, a magnesium-containing phosphate binder may be added in conjunction with a reduction in the dialysate magnesium concentration (in the dialysis population). These agents should not be considered first-line therapy for control of phosphorus, and careful monitoring of magnesium is warranted if therapy is started.

More aggressive control of W.K.'s serum phosphorus is needed to lower serum phosphorus toward normal levels. Currently, W.K. is taking a calcium-based phosphate binder. Although presumably much of this calcium will be bound to phosphorus in the GI tract, a potential exists for calcium absorption. Furthermore, her serum calcium levels are in the upper range of normal not corrected. Sevelamer should be started to limit her calcium exposure and decrease her phosphorus levels. The recommended starting dose is 800 mg TID with meals, titrated based on follow-up phosphorus values. Adjustments should also be considered in conjunction with vitamin D therapy (see Vitamin D section). W.K. should be instructed to take her phosphate binder with meals. This regimen should be implemented in conjunction with a restricted-phosphorus diet. Regular reinforcement of the importance of compliance is necessary because nonadherence with prescribed dietary phosphorus restriction and drug therapy is one of the most significant factors associated with treatment failure. Use of a low-calcium dialysate may also help decrease her risk of hypercalcemia.

VITAMIN D

Nutritional Vitamin D

Nutritional vitamin D (NVD) occurs naturally as ergocalciferol (vitamin D_2)

obtained from dietary sources and as cholecalciferol (vitamin D_3) obtained from dietary sources and activated in the skin by sunlight in mammals, both of which are inactive precursors of active forms of vitamin D. An intermediate activation step (25-hydroxylation) occurs in the liver to produce 25-hydroxy vitamin D (25-hydroxycalciferol), which is also relatively inactive (Fig. 28-2). Final activation (1-hydroxylation) occurs in the kidney, yielding calcitriol (1,25-dihydroxycholecalciferol), the active form of vitamin D. Thus, the response to vitamins D_2 and D_3 in patients with compromised kidney function can vary, depending on the degree of kidney dysfunction and the ability of the kidney to metabolize 25-hydroxyvitamin D to calcitriol. Decreased levels of 25-hydroxyvitamin D occur in the early stages of CKD, reducing substrate for producing calcitriol.[91] Altered vitamin D metabolism that occurs in this population warrants measurement of 25-hydroxyvitamin D and supplementation with NVD. Oral therapy with active vitamin D (oral calcitriol) or an analog (oral doxercalciferol) is likely warranted only when PTH remains elevated despite normal 25-hydroxyvitamin D levels.[91] As the final, active metabolite of vitamin D, calcitriol (or another activated form of vitamin D) is usually required in patients with more severe kidney disease (CKD 4–5).

Several small studies have shown that the benefits of NVD administration extend beyond bone and mineral metabolism. Reduction in ESA doses, improved glycemic control, reduced activated vitamin D administration, and inflammation modulation are benefits observed from NVD supplementation in dialysis patients.[148,149] Although some effects have been repeated in different studies, randomized control trials are needed to confirm these benefits.

Vitamin D Receptor Agonist

Calcitriol

Administration of vitamin D receptor agonist (VDRA), active vitamin D, in conjunction with control of serum phosphorus and calcium, is necessary in many patients with CKD to manage CKD-MBD. Calcitriol interacts with the vitamin D receptor (VDR) located in the parathyroid gland, intestines, bone, and kidney. It is thought to decrease PTH messenger RNA, resulting in decreased PTH secretion. In addition, calcitriol stimulates calcium absorption from the GI tract to correct hypocalcemia and prevent SHPT. In order to avoid hypercalcemia, the lowest effective dose should be used, and the patient’s serum calcium should be monitored at least every 2 weeks for 1 month and then monthly thereafter. Furthermore,

---

control of serum phosphorus is critical before calcitriol is initiated, as vitamin D increases GI phosphorus absorption.

Calcitriol is available as an oral formulation (Rocaltrol) or IV formulation (Calcijex). Administration of calcitriol by either the oral or IV route may be based on conventional dosing (usually 0.25–0.5 mcg/day) or pulse dosing (intermittent dosing of 0.5–2.0 mcg 2–3 times/week). Higher doses (e.g., 4 mcg 3 times/week) are generally required to reduce PTH secretion in more severe SHPT (PTH >1,000 pg/mL). Daily dosing of 0.25 to 0.5 mcg may be preferred in patients with hypocalcemia because this regimen primarily works to stimulate calcium absorption from the GI tract. Intermittent dosing of IV calcitriol is routine in the HD population because administration is coordinated with dialysis. In contrast, oral dosing is more convenient in patients with CKD who are not having dialysis and the PD population. Intact PTH and serum calcium concentrations are used to determine starting doses and dosing adjustments for calcitriol. Changes in Medicare have resulted in more outpatient hemodialysis units utilizing oral activated vitamin D therapy.

Intact PTH (1–84 PTH) is the 84-amino acid biologically active form of this hormone. It is metabolized into smaller, less-active fragments (e.g., 7–84 PTH) with activity that is not well characterized. These fragments are cleared from the circulation by the kidney and may accumulate in patients with CKD. Assays used for iPTH measure the intact structure as well as the biologically active and inactive PTH fragments. Thus, proposed ranges for iPTH in current guidelines are based on these assays. Assays that measure only the biologically active form (1–84 biPTH) have become available (third-generation assays). When iPTH is measured using both methods, there is roughly a 2:1 ratio between the second- and third-generation assay results. An iPTH of 150 pg/mL would correspond to a biPTH 75 pg/mL.[150] These assays correlate very well and the third-generation assay offers no advantage over the widely used second-generation assay. Clearly, the clinician must know which assay has been used to appropriately interpret the results, establish the desired PTH range, and correctly adjust therapy.

The KDIGO guidelines vary as they recommend iPTH levels to be maintained within the normal limits in CKD 3 and 4. However, the CKD 5D iPTH target range is 2 to 9 times the upper normal limits, approximately 150 to 600 pg/mL.

Dose adjustments of calcitriol are generally made in 0.5- to 1.0-mcg increments every 2 to 4 weeks in the early stages of therapy until iPTH and serum calcium are maintained at target levels. If hypercalcemia develops, the decision to withhold therapy or to switch to a less hypercalcemic VDRA must be made. Serum iPTH should be monitored every 3 to 6 months, and adjustments of calcitriol doses made to maintain the goal iPTH and to prevent hypercalcemia and hyperphosphatemia.

Paricalcitol

The unique interactions of vitamin D with the VDR led to the development of designer vitamin D analogs, which vary in their affinity for the VDR. In the case of treatment for SHPT, some were developed to retain the suppressive effect on PTH release while decreasing the potential for hypercalcemia relative to calcitriol. Currently approved agents for managing SHPT in the United States are paricalcitol

(Zemplar), also referred to as 19-nor-1,25-dihydroxyvitamin D_2, and doxercalciferol (Hectorol), or 1-α-hydroxyvitamin D_2. Doxercalciferol requires conversion to the active form (1-α-,25-dihydroxyvitamin D_2) by the liver.

In patients with SHPT, paricalcitol significantly decreases iPTH without significantly increasing calcium or phosphorus. Paricalcitol is approximately 10-fold less hypercalcemic and hyperphosphatemic than calcitriol.[151,152] The initial dose of IV paricalcitol is 0.04 mcg/kg to 0.1 mcg/kg (2.8–7 mcg) administered with each dialysis session or every other day.[153] Oral paricalcitol capsules are available in three strengths (1, 2, and 4 mcg) administered daily or 3 times weekly. The starting dose should be 1 mcg daily or 2 mcg 3 times weekly if the baseline iPTH level is 500 pg/mL or less, and 2 mcg daily or 4 mcg 3 times weekly if the iPTH is greater than 500 pg/mL. Some data have also suggested paricalcitol dosing based on initial PTH levels (paricalcitol dose = PTH/80) rather than weight as a reasonable dosing strategy.[153] Doses can be titrated every 2 to 4 weeks based on iPTH values.

The recommended conversion ratio for calcitriol to paricalcitol is 1:4 (i.e., for every 1 mcg of calcitriol, 4 mcg of paricalcitol should be administered). This information is based on similar efficacy observed when patients treated for SHPT with calcitriol were switched to paricalcitol using this dosing strategy.[151,152] A lower ratio of 1:3 also has been proposed in patients resistant to therapy with calcitriol.

Doxercalciferol

Doxercalciferol, another vitamin D analog, is an alternative to calcitriol and has been studied in patients with CKD 5D. Doxercalciferol has similar effects on PTH as the other vitamin D analogs; however, it increases phosphorus and calcium to a greater degree than paricalcitol.[154] Doxercalciferol is available as a capsule and IV injection. The doses were 4 mcg IV or 10 mcg orally 3 times a week with HD. Oral and IV therapy are both effective in reducing iPTH levels in patients with SHPT; however, some evidence indicated that intermittent IV therapy may result in less hypercalcemia and hyperphosphatemia than oral intermittent therapy.[155] The recommended starting dose of doxercalciferol for patients on dialysis is 4 mcg IV or 10 mcg orally administered 3 times a week with dosing titration based on changes in iPTH.[156,157]

Vitamin D analogs offer an alternative for patients in whom persistent hypercalcemia develops with calcitriol therapy. Use of these agents is increasing in clinical practice because of the concerns of hypercalcemia and its adverse consequences. Repeated observational reports indicate lower overall and cardiovascular-related mortality rates with activated vitamin D therapy, regardless of the agent received, than in those not receiving vitamin D therapy.[158] Two trials also examined survival advantages among the different forms of vitamin D in patients on HD. One report indicated that receiving paricalcitol for 36 months conferred a survival advantage starting at 12 months from initiation of therapy and increased with time compared with those receiving calcitriol. Another study reported that patients taking either paricalcitol or doxercalciferol had a significantly lower mortality rate than patients receiving calcitriol, although when adjusted for laboratory values and clinic standardized mortality, no difference was found between the products.[158]

Possible biologic reasons for vitamin D improving outcomes include its role in downregulating the RAAS and immunomodulatory properties. A prospective trial would be required to confirm a survival advantage associated with vitamin D therapy.

CALCIMIMETICS

Calcimimetic agents increase the sensitivity of the calcium-sensing receptors (CaSR) to extracellular calcium ions and inhibit the release of PTH, lowering PTH levels within hours after administration. The discovery of extracellular CaSR prompted research with calcimimetic agents that allosterically modulate CaSR. CaSR are located in the parathyroid gland, thyroid, nephron, brain, intestine, bone, lung, and other tissues.[159] The calcimimetic cinacalcet is the first agent in this class to be approved by the FDA to treat SHPT in ESRD.[160] Cinacalcet is an effective agent at reducing and sustaining iPTH within target concentrations in HD patients.[161] Cinacalcet offers an additional choice of agent to lower PTH when vitamin D cannot be increased because of elevated calcium or phosphorus. The EVOLVE trial was a randomized clinical trial comparing cinacalcet to placebo in 3,883 dialysis patients with

a primary outcome of death, cardiovascular events, or hospitalizations. Patients were eligible to receive phosphate binders or vitamin D analogs in either arm. There was 7% nonsignificant reduction in primary end points in the cinacalcet group.[162] However, issues plagued the large trial as several patients in the placebo arm actually received cinacalcet therapy. The survival benefits of cinacalcet remained undetermined. Cinacalcet is not FDA approved for use in CKD patients not receiving dialysis because it is associated with frequent hypocalcemic episodes.[163]

Appropriate treatment for W.K. should be based on assessment of her serum calcium, phosphorus, and PTH values. She currently has an elevated PTH, phosphorus, and calcium; therefore, cinacalcet should be started in conjunction with her dietary phosphorus restriction, phosphate binder regimen, and vitamin D therapy. Cinacalcet should be initiated at a dose of 30 mg daily, with dosage titrations occurring every 2 to 4 weeks to 60, 90, 120, or a maximum of 180 mg daily to achieve target iPTH levels. Serum calcium and phosphorous levels should be drawn within 1 week after initiation or dosage increase, and plasma PTH levels drawn within 4 weeks after initiation of therapy or dosage adjustment. Nausea and vomiting are the most common adverse events associated with cinacalcet. Nausea is twice as likely to occur at any dose, while vomiting is more frequent at higher doses.[162] In phase III trials, 66% of patients receiving cinacalcet experienced at least one episode of hypocalcemia (serum calcium <8.4 mg/dL), although less than 1% of patients discontinued treatment.[164] The high incidence of hypocalcemia is not solely caused by lowered PTH activity but is also attributed to the mechanism of action of cinacalcet. It is thought that activation of CaSR in bone, intestine, and other tissues may contribute to hypocalcemia. Most episodes of hypocalcemia occur during the initiation of cinacalcet therapy, and slowly titrating the dose reduces the risk. Seizures caused by hypocalcemia have been reported. Vitamin D or calcium-based phosphate binders can be used to increase serum calcium levels between 7.5 and 8.4 mg/dL. If serum calcium falls below 7.5 mg/dL and is associated with symptoms of hypocalcemia and vitamin D cannot be increased further, cinacalcet should be withheld until serum calcium normalizes or the patient is asymptomatic. Cinacalcet is a strong in vitro inhibitor of cytochrome P-450 isoenzyme CYP2D6; therefore, dose adjustments of concomitant medications that are predominantly metabolized by CYP2D6 may be required. Cinacalcet is also a substrate of CYP3A4, and ketoconazole, a potent inhibitor of CYP3A4, has been shown to increase the area under the curve of cinacalcet 2.3 times. Thus, other inhibitors of the CYP3A4 isoenzyme should be used with caution in patients receiving cinacalcet.[160]

PARATHYROIDECTOMY

The parathyroid glands enlarge as a compensatory response to disturbances of phosphorus, calcium, and calcitriol metabolism in patients with CKD. Timely administration of vitamin D therapy to prevent parathyroid hyperplasia is crucial as treatment with vitamin D cannot adequately reverse established hyperplasia. A parathyroidectomy is often reserved for patients with severe hyperparathyroidism with PTH values greater than 1,000 pg/mL, concomitant hypercalcemia, and failure to respond to pharmacologic therapy.[91] Parathyroidectomy can be subtotal, total, or total with autotransplantation. One of the major complications of parathyroidectomy is the early development of postsurgical hypocalcemia.[165] Clinical symptoms of hypocalcemia include muscle irritability, fatigue, depression, and memory loss. Patients should be monitored closely after parathyroidectomy, and all patients with signs or symptoms of hypocalcemia should be treated with calcium supplementation (see Chapter 27, Fluid and Electrolyte Disorders). In patients who have had subtotal parathyroidectomy, the remaining parathyroid tissues will start functioning adequately, so the acute hypocalcemia is transient, lasting only a few days. Hypocalcemia is permanent in total parathyroidectomy and requires long-term treatment with calcitriol and oral calcium supplements (1–1.5 g/day of elemental calcium). Studies investigating SHPT management with cinacalcet report reduced rates of parathyroidectomy surgeries.[162,166]

OTHER COMPLICATIONS OF CKD

Endocrine Abnormalities Caused by Uremia

CASE 28-3, QUESTION 3: Does W.K.'s hypothyroidism have any relationship to her CKD? What other endocrine abnormalities are associated with uremia?

Disturbances in thyroid function are frequently encountered in patients with CKD because the kidney is involved in all aspects of peripheral thyroid hormone metabolism. Common laboratory abnormalities include reduced serum concentrations of total thyroxine (T_4) and 3,5,3′-triiodothyronine (T_3) and a low free thyroxine index (FTI). The thyroid-stimulating hormone (TSH) concentration is usually normal, but peripheral conversion of T_4 to T_3 is reduced in uremic patients.[167] Despite these abnormalities, clinical hypothyroidism does not occur solely as a result of kidney disease, probably because the amount of free (unbound to protein) thyroid hormone in serum remains normal. Hypothyroidism in patients with kidney failure should be confirmed by the presence of an elevated serum TSH concentration and a low serum concentration of free T_4.

Other endocrine abnormalities that have been observed in patients with CKD include gonadal dysfunction leading to impotence, diminished testicular size, menstrual abnormalities, and cessation of ovulation.[168] Decreased libido and infertility occur in both sexes. Uremic women of childbearing age should be counseled on the risk of becoming pregnant because of the multiple complications of pregnancy in ESRD, including high termination rates.[169]

Altered Glucose and Insulin Metabolism

CASE 28-3, QUESTION 4: Other than the obvious effect of W.K.'s diabetes mellitus on blood glucose, are there any effects of kidney disease itself on glucose metabolism?

Uremia often is associated with glucose intolerance early in the course of kidney disease in nondiabetic patients. Specifically, patients with CKD often exhibit an abnormal response to an oral glucose challenge and have sustained hyperinsulinemia.[170,171] The fasting blood glucose is typically within normal limits. Diminished tissue sensitivity to the action of insulin is also observed. Inflammation and oxidative stress are likely contributors predisposing CKD patients to insulin resistance.[172] Most nondiabetic patients with kidney disease do not require therapy for hyperglycemia, and dialysis can correct these abnormalities in glucose metabolism.

Patients with diabetes mellitus and advanced kidney disease may experience improved glucose control and decreased insulin requirements. This is because the kidney is responsible for a substantial amount of daily insulin degradation and, as the disease progresses, less insulin is cleared and its metabolic half-life is increased. A decreased clearance of insulin by muscle tissue also can occur in patients with uremia.[173] Thus, in diabetic patients with progressive kidney disease, blood glucose concentrations

should be monitored and insulin doses adjusted to avoid hypoglycemia. W.K. has CKD 5D and is receiving her insulin in the peritoneal dialysate solution. Hyperglycemia is also a concern in W.K. because the glucose present in her continuous ambulatory peritoneal dialysis (CAPD) fluid to promote fluid removal will be absorbed systemically. Insulin dosage adjustments should be made on the basis of repeated home blood glucose measurements, changes in the CAPD prescription, and glycosylated hemoglobin determinations.

Gastrointestinal Complications

CASE 28-3, QUESTION 5: One month before her current clinic visit, W.K. complained of nausea and vomiting of partially digested food. Metoclopramide (Reglan) was begun at that time. Could W.K.'s nausea and vomiting have been caused by her kidney failure? Was the appropriate therapy selected?

GI abnormalities are extremely common in patients with CKD and include anorexia, nausea, vomiting, hiccups, abdominal pain, GI bleeding, diarrhea, and constipation. Diminished gastric motility can occur from uremia; however, this problem may improve with adequate HD. Dyspeptic complaints and gastroparesis may be more prevalent in the PD population than in the HD population and in the earlier stages of CKD.[174] W.K. has diabetes and diabetic neuropathy, which also contributes to the delayed gastric emptying (diabetic gastroparesis) and retention of food in the upper intestinal tract. This frequently causes distension, nausea, and vomiting. Metoclopramide is recommended to relieve these symptoms, although the risk for extrapyramidal side effects should be considered. A lower dose of 5 mg before meals may be warranted for W.K.

Severe uremia also causes nausea and vomiting, and these can be initial presenting symptoms of kidney failure. At this stage of clinical presentation, dialysis is the preferred therapy. Drug-induced nausea and vomiting always should be considered because patients with CKD often take multiple drugs and are at risk for drug toxicity because of diminished kidney function (e.g., digitalis intoxication).

BLEEDING

CASE 28-3, QUESTION 6: During her clinic visit, W.K. reports that her bowel movements have become black and tarry in appearance. A rectal examination reveals guaiac-positive stools. Is GI bleeding related to kidney failure?

W.K. should be evaluated for peptic ulcer disease and lower GI bleeding. Uremic patients are at risk for bleeding from mucosal surfaces such as the stomach. Angiodysplasia of the stomach and duodenum, as well as erosive esophagitis, are the most common causes of bleeding in patients with CKD.[175] Treatment of upper GI bleeding in uremic patients usually consists of cautious use of H_2-receptor antagonists, which should be given in reduced doses according to the degree of kidney function. Proton-pump inhibitors are primarily eliminated by nonkidney routes and can be administered at standard doses (see Chapter 23, Upper Gastrointestinal Disorders).

Dermatologic Complications

Several dermal abnormalities have been observed in patients with CKD, including hyperpigmentation, abnormal perspiration, skin dryness, and persistent pruritus. Of these, uremic pruritus can be the most bothersome for the patient and may lead to repeated scratching and skin excoriation. Hyperparathyroidism, hypervitaminosis A, and dermal mast cell proliferation with subsequent histamine release have been suggested as causes of pruritus.[176]

Treatment of pruritus often is a frustrating experience for the patient and clinician. Although many therapies have been advocated, few have provided sustained benefit. A trial-and-error approach is recommended. Efficient dialysis therapy relieves pruritus in some patients and pharmacologic therapy may be avoided. When necessary, initial pharmacologic treatment usually consists of oral antihistamines (e.g., hydroxyzine). Topical emollients or topical steroids may provide benefit if antihistamine therapy is not completely successful. If pruritus is still present, other treatment options can be tried. These include cholestyramine, ultraviolet B phototherapy, and oral administration of activated charcoal. Control of calcium, phosphorus, and PTH concentrations is also advocated to reduce pruritus in patients with CKD.[176]

GLOMERULAR DISEASE

Glomerular diseases lead to many complications that result from disruption of normal glomerular structure and function. Several clinical syndromes of glomerular disease exist; however, GN, characterized as proliferation and inflammation of the glomerulus, is observed most frequently. According to the most recent USRDS report, GN as a broad category remains the third leading cause of ESRD in the United States.[3] In developing countries, ESRD caused by GN is more common as a result of various infectious processes causing kidney failure.

Nephrotic Syndrome

Nephrotic syndrome is characterized by proteinuria greater than 3.5 g/day, hypoalbuminemia, edema, and hyperlipidemia. In more severe conditions, hypercoagulable conditions are increased from a loss of hemostasis control proteins, including antithrombin III, protein S, and protein C. This syndrome can occur with or without a change in GFR. Nephrotic syndrome may be caused by a primary disease, such as membranous glomerulopathy, which is characterized by deposition of immune complexes, or other systemic diseases including diabetic glomerulosclerosis and amyloidosis. Elevated serum cholesterol and triglycerides are observed in patients with this degree of proteinuria (>3.5 g/day). This hyperlipidemic condition also predisposes patients with nephrotic syndrome to accelerated atherosclerosis. Hyperlipidemia itself can also contribute to progression of kidney disease. Because nephrotic syndrome is associated with numerous causes, further evaluation of the patient for systemic causes is required to determine the course of therapy and prognosis.

Chronic Glomerulopathies

GN can occur as a primary disease that is idiopathic in origin (e.g., focal segmental glomerulosclerosis [FSGS]) or as a secondary manifestation of other systemic disease (e.g., lupus nephritis [LN], Wegener granulomatosis). Kidney biopsy is often required for definitive diagnosis. Glomerular lesions associated with glomerulopathies are characterized as diffuse, focal, or segmental, depending on the extent of involvement of individual glomeruli. Pathologic changes are characterized as proliferative, membranous, and sclerotic based on the pattern observed. Proliferative changes usually involve an overgrowth of the epithelium or mesangium, whereas membranous changes are typically described as a thickening of the glomerular basement membrane. Signs and symptoms of GN include hematuria, proteinuria, and decreased kidney function. An autoimmune reaction is the predominant pathogenic process leading to most forms of primary and secondary GN. Although a number of autoantibodies are associated with GN, their exact role in the pathogenesis of GN is still unclear.[177]

Glomerular damage generally occurs in two phases: acute and chronic. During the acute phase, immune reactions occur within glomeruli that stimulate the complement cascade, ultimately resulting in glomerular damage. Nonimmune mechanisms that occur in response to loss of nephron function and hyperfiltration of remaining nephrons are characteristic of the chronic phase.

GN often causes acute kidney failure. Patients with damage to more than 50% of glomeruli in the presence of rapid loss in kidney function (over the course of days to weeks) are classified as having rapidly progressive glomerulonephritis (RPGN).[178] If kidney involvement is severe, signs and symptoms of uremia may develop. RPGN may be classified based on the immunopathogenic etiology of the glomerular damage: (a) immune complex deposition (e.g., LN); (b) nonimmune deposit-mediated mechanism (e.g., Wegener granulomatosis); and (c) sclerotic lesions of the glomerulus (e.g., FSGS).[177] This chapter focuses on the treatment of the more common forms of chronic GN (i.e., LN, Wegener granulomatosis, FSGS).

LUPUS NEPHRITIS

Systemic lupus erythematosus (SLE) is a multisystem autoimmune disease characterized by abnormalities in cell-mediated immunity, such as B-cell hyperresponsiveness and defective T-cell–mediated suppressor activity. In certain predisposed individuals, SLE can lead to the development of LN, a secondary form of GN. LN is the prototypical immune complex–mediated kidney disease, characterized by deposition or in situ formation of autoantibody–antigen complexes along the glomerular capillary network. LN remains an important cause of mortality. Up to 60% of adults with SLE have some degree of kidney involvement later in the course of their disease, discernible from clinical evidence of kidney damage: heavy proteinuria, hematuria, decreased eGFR, and hypertension. Early in the disease, laboratory abnormalities indicative of kidney involvement are seen in approximately 25% to 50% of patients[177] (see also Chapter 33, Systemic Lupus Erythematosus).

CASE 28-4

QUESTION 1: S.L., a 34-year-old black woman with a 7-year history of SLE, presents to the nephrology clinic for follow-up of LN. BP of 160/95. Pertinent laboratory values are as follows:

Serum Na, 146 mEq/L
K, 4.2 mEq/L
Cl, 100 mEq/L
CO_2 content, 25 mEq/L
SCr, 2.0 mg/dL
BUN, 20 mg/dL
WBC count, 9,600/µL

RBC indices are normal. Platelet count is 175,000/µL. Her 24-hour urine contains 2.3 g of albumin (normal, <30 mg/day), and her urine analysis shows 12 RBCs/high-power field (HPF) (normal, 0–3). Compared with her visit of a week ago, S.L.'s kidney function and urinary indices (proteinuria, hematuria) show substantial worsening of her nephritis. S.L. was hospitalized, and a kidney biopsy showed inflammation of 40% of the glomeruli. What subjective and objective data in S.L. are consistent with a diagnosis of LN, and what is the stage of her nephritis?

S.L. has clinical evidence of kidney damage as demonstrated by her proteinuria, hematuria, and a slightly increased SCr concentration. Glomerular damage is most evident by the presence of RBC or red cell casts in the urine, a finding observed in S.L.

Classifications

The International Society of Nephrology and the Renal Pathology Society (ISN/RPS) classification system was developed in 2003 to replace the previous classification system published by the World Health Organization (Table 28-11).[179] This classification scheme provides a reasonable correlation among histopathology, outcome, and response to treatment. S.L. has proteinuria, hematuria, and inflammation of less than 50% of her glomeruli, and she is diagnosed as having class III/A (focal proliferative) GN.

Table 28-11

2003 International Society of Nephrology/Renal Pathology Society Classification of Lupus Nephritis[177]

Class	Histologic Characterization	Usual Clinical Presentation
I	Minimal mesangial lupus nephritis	Mild proteinuria
II	Mesangial proliferative glomerulonephritis	Mild proteinuria and urine sediment abnormalities
III	Focal and segmental proliferative glomerulonephritis A: active lesions; A/C: active and chronic lesions; C: chronic lesions	Proteinuria and hematuria
IV	Diffuse proliferative segmental (S) or global (G) glomerulonephritis A: active lesions; A/C: active and chronic lesions; C: chronic lesions	Heavy proteinuria; active sediment; hypertension; renal failure
V	Membranous glomerulonephritis	Proteinuria; often nephrotic syndrome
VI	Advanced sclerosing glomerulonephritis	Proteinuria; renal failure; nephrotic syndrome

Data from the 2003 International Society of Nephrology/Renal Pathology Society Classification of Lupus Nephritis.

Treatment

CASE 28-4, QUESTION 2: Should S.L.'s LN be treated?

Unlike nonkidney manifestations of SLE, serologic markers of disease correlate poorly with LN. Therefore, elevations in SCr, hypertension, proteinuria and hematuria, as seen in S.L., are used as primary markers of disease activity.

Treatment of LN must address both management of the acute disease process and maintenance therapy for the more stable chronic disease process. A general consensus is that patients, such as S.L., who present with focal or diffuse proliferative GN (class III or IV) should be treated aggressively, with the primary goal of preventing irreversible kidney damage. The prognosis of kidney function in patients with SLE has improved. However, the prognosis is worse in blacks when compared with the white population treated for SLE.[180] Elevated SCr, heavy proteinuria, anemia, and disease onset during childhood or in those older than 60 years of age are other predictors of a worse prognosis. Advances in pharmacologic therapy (i.e., safer immunosuppressive regimens and antihypertensives) have improved the prognosis for the population as a whole.

The treatment of LN is primarily empiric but is based, to some extent, on histologic findings. The KDIGO Clinical Practice Guideline for Glomerulonephritis provides recommendations for treatment based on disease activity.[177] Although appropriate treatment can improve patient outcomes, vigorous attempts to suppress SLE activity may lead to serious drug-related complications.

The primary strategy in the treatment of LN involves suppression of the immune system with corticosteroids and cytotoxic agents, such as cyclophosphamide (CYC), azathioprine (AZA), calcineurin inhibitor (CNI) therapy (cyclosporine or tacrolimus) and mycophenolate mofetil (MMF). Clinicians need to be aware of the potential complications associated with these therapies and carefully monitor patients to determine the indication for treatment and improved prognosis. Toxicities associated with immunosuppressive agents depend on both the dose and the duration of therapy. Abnormalities in hematopoiesis, such as neutropenia and thrombocytopenia, are the most common adverse effects associated with cytotoxic agents. Immunosuppression, in general, increases a patient’s susceptibility to a vast array of infections and to lymphocytic malignancies. In addition, the alkylating agent CYC can cause nausea and vomiting, gonadal toxicity, hemorrhagic cystitis, and alopecia. The risk versus benefit of CYC use has to be seriously weighed in young women who are considering pregnancy in the future. The antimetabolite AZA can cause pancreatitis and abnormalities in liver function. The selective inhibitor of inosine monophosphate dehydrogenase, MMF, although relatively benign compared with the other agents, can cause GI disturbances.

Induction Therapy

Therapy for LN is usually not indicated in patients with normal kidney function and proteinuria less than 1 g, because these patients have a good prognosis. Corticosteroids represent the cornerstone of therapy in patients with a mild form of LN. Prednisone (1 mg/kg or methylprednisolone) should be initiated for patients with class II LN with proteinuria >3 g/day or CNI. In patients with a more severe form (class III and IV), prednisone 1 mg/kg/day combined with either CYC or MMF should be initiated. For the treatment of acute exacerbations of LN, high-dose pulse therapy with methylprednisolone may be warranted. Given that S.L.’s LN has worsened, she should receive pulse methylprednisolone (0.5–1 g IV, not to exceed 1 g) for 3 days in an attempt to reduce the degree of proteinuria and improve kidney function.[177] Although generally well tolerated, rapid methylprednisolone injections can cause transient tremor, flushing, and altered taste sensation. To reduce the risk of adverse effects associated with the rate of injection, S.L. should receive methylprednisolone for 30 minutes. After a course of pulse methylprednisolone therapy, oral prednisone at a dose 10 to 20 mg daily may be initiated.[177] Suppression of S.L.'s active LN should be demonstrated by a reduction in proteinuria and hematuria and an increase in her eGFR.

The addition of cytotoxic agents is reserved for patients who do not respond to corticosteroids alone, or those who have unacceptable toxicity to corticosteroids, worsening kidney function, severe proliferative lesions, or evidence of sclerosis on kidney biopsy. Induction therapy with six monthly pulse doses of IV CYC (0.5–1 g/m^2) or six doses of CYC given every 2 weeks at a dose of 0.5 g/m^2 along with steroid therapy was shown to have improved kidney outcomes with fewer flares and relapses.[177] Before and for 24 hours after initiating IV CYC, the patient must be well hydrated to prevent bladder toxicity. Alternatively, MMF (2,000–3,000 mg/day times 6 months) or TAC (0.06–0.1 mg/kg/day) has been proven to be as effective as CYC in the induction treatment for LN.[181,182] Given the significant toxicities associated with CYC (e.g., gonadal toxicity and hemorrhagic cystitis), MMF or tacrolimus are attractive options given their antiinflammatory properties and the lower side effect profile. Recently, rituximab, an anti-CD20 monoclonal antibody, has demonstrated similar efficacy as MMF and CYC.[183]

Maintenance Therapy

Once the acute flare resolves (generally in up to 12 weeks), low-dose, maintenance steroid therapy with 5 to 15 mg/day of prednisone can be initiated in combination with cytotoxic therapy, if indicated, based on the severity of LN. In a meta-analysis assessing the efficacy of therapeutic agents used to treat LN, improved outcomes (total mortality and ESRD) were associated with use of oral prednisone in combination with IV CYC. As a result, the National Institutes of Health recommends the use of IV CYC pulse therapy (0.5–1 g/m^2) every 3 months for up to 2 years for maintenance therapy of LN.[177] An additional benefit of combination therapy with immunosuppressive agents is their steroid-sparing effect and, potentially, lower risk of steroid toxicity.

Steroid and CYC free regimens are often desired to avoid steroid and CYC adverse events. Studies have evaluated other immunosuppressive agents (AZA, MMF) for maintenance therapy in light of the toxicities associated with CYC or steroids. The KDIGO Clinical Practice Guideline for Glomerulonephritis recommends AZA (1.5–2.5 mg/kg/day) or MMF (1–2 g/day) and low-dose corticosteroids (≤10 mg/day prednisone equivalent) for maintenance therapy.[177]

A multi-regimen trial compared maintenance therapy with AZA (1–3 mg/day) and MMF (500–3,000 mg/day) with CYC along with steroids after induction with CYC in patients with severe LN. Patients receiving AZA had a lower mortality rate than those treated with CYC, and the MMF treatment group had fewer relapses than the CYC treatment group.[184] MMF and AZA may be indicated in patients resistant to CYC therapy or with a more severe type of LN (class III and IV). The addition of

AZA or MMF, along with corticosteroid therapy, should be considered in S.L. once the acute lupus flare resolves. Once suppression of S.L.'s LN is documented, initiation of either AZA or MMF and steroids is indicated because of the severity of her LN (class III). The duration of therapy is dictated by the individual's response, but typically patients will require up to 2 years of maintenance therapy.

Alternative Agents

The KDIGO practice guidelines recommend reserving CNI for those intolerant to MMF or AZA as maintenance therapy.[177] Rituximab, a monoclonal antibody that inhibits B-cell production, is being studied because B-cell hyperactivity is one of the major pathophysiologic mechanisms of LN. Small studies in patients with LN resistant to therapy have shown rituximab to be of benefit. Cyclosporine, in doses of 5 mg/kg/day, may also provide an alternative therapy to treat lupus in the maintenance phase in patients unresponsive to treatment.[177]

WEGENER GRANULOMATOSIS

CASE 28-5

QUESTION 1: J.M. is a 42-year-old white man who presents to the clinic with a 1-month history of cough, nasal congestion, facial pain with headache, fever, and lethargy. During the past week, he has noted bright red blood in his phlegm, which has worsened in the past 3 days. Pertinent laboratory values are as follows:

Serum Na, 143 mEq/L
K, 5.1 mEq/L
Cl, 102 mEq/L
CO_2 content, 24 mEq/L
SCr, 2.8 mg/dL
BUN, 41 mg/dL

This compares with last year's physical checkup visit when his SCr and BUN were within the normal range. Hematologic studies reveal an Hct of 35%, an Hgb of 11.7 g/dL, a mean corpuscular volume of 69 μL, a mean corpuscular Hgb concentration of 24%, and a reticulocyte count of 1.8%. RBC indices are normal, and the platelet count is 175,000/μL. His 24-hour urine contains 3.8 g of albumin (normal, <30 mg), and his eGFR is calculated to be 27 mL/minute/1.73 m^2. His urine also contains many RBC casts and 16 RBCs/HPF (normal, 0–3 RBCs/HPF). Chest radiograph shows alveolar shadowing spreading from the hilar region. The result of J.M.'s cytoplasmic-staining, antineutrophil cytoplasmic antibody (c-ANCA) is positive. On the basis of his subjective and objective data, which of the chronic glomerulopathies is J.M. likely to have?

Wegener granulomatosis is a primary systemic vasculitis characterized by granulomatous inflammation of the upper and lower respiratory tract and secondary GN. Primary systemic vasculitic syndromes, such as Wegener granulomatosis, often cause GN. Although vasculitis involves inflammation of blood vessels of any size, the small- and medium-size vessels are most commonly affected.[185] The etiology of

Wegener granulomatosis is unclear; however, an autoimmune response is suspected for two reasons. First, Wegener granulomatosis is a systemic inflammatory disease without a known infectious etiology. Second, good treatment response can be obtained with immunosuppressive therapy.

The clinical features of Wegener granulomatosis include upper airway disease, such as sinusitis, epistaxis, and nasopharyngitis, as well as otitis media caused by blockage of the eustachian tube. Constitutional symptoms include fever, night sweats, arthralgia, anorexia, and malaise. After a few months, weakness may progress, severely limiting physical activity. Although the lungs are invariably affected, most patients remain asymptomatic; however, cough and hemoptysis may be present. J.M.'s presenting symptoms are consistent with the above clinical features. The laboratory signs also are nonspecific and indicate the presence of a systemic inflammatory process. They include an elevated erythrocyte sedimentation rate in virtually all patients, anemia of chronic disease, and thrombocytosis.[185] Hematuria and proteinuria can be prominent features of Wegener granulomatosis and are present on initial presentation in 80% of patients. The presence of severely diminished kidney function, seen in approximately 10% of patients, is an ominous sign, with nearly one-third of these patients progressing to ESRD. All patients with Wegener granulomatosis are at risk of developing irreversible, rapidly progressive kidney failure. Kidney histologic findings are nonspecific, with most patients exhibiting necrotizing crescentic GN.[185]

Wegener granulomatosis is diagnosed primarily by the presenting signs and symptoms. According to the American College of Rheumatology 1990 classification, a person is diagnosed with Wegener granulomatosis if any two of the following four criteria are present: (a) nasal or oral inflammation, (b) abnormal chest radiograph, (c) microhematuria (>5 RBCs/HPF) or RBC casts in the urine sediment, or (d) granulomatous inflammation on biopsy.[185] J.M. has satisfied three of the four criteria for diagnosing Wegener granulomatosis.

Treatment

CASE 28-5, QUESTION 2: How should J.M.'s Wegener granulomatosis be treated?

The discovery of c-ANCA and its strong association with Wegener granulomatosis has permitted a more certain diagnosis. Because of the substantial rise in titer that commonly precedes relapse of Wegener granulomatosis, the c-ANCA test is best used to follow the course of disease activity and guide induction of therapy. Treatment with CYC and corticosteroids results in improvement in kidney function in approximately 80% to 85% of patients, versus 75% with pulse steroids alone.[177] The main predictive factors for treatment success are the extent of kidney damage before therapy starts and how long therapy is delayed after symptoms develop.

Cyclophosphamide

Because Wegener granulomatosis is considered an autoimmune inflammatory disease, immunosuppressive therapy is the mainstay of treatment. Table 28-12 list KDIGO guidelines-recommended treatment regimens. Therapy is generally indicated for 6 months if remission occurs and up to 12 months in resistant cases.[185] J.M. should be started on oral CYC 2 mg/kg/day, as a single morning dose, and corticosteroids to prevent irreversible glomerular scarring. High fluid intake (>3 L/day) and mesna reduce the risk of hemorrhagic cystitis. Regular UA should be performed (every 3–6 months) to detect hematuria caused by hemorrhagic cystitis.

Table 28-12

Recommended Treatment Regimens for ANCA Vasculitis with GN[177]

Agent	Route	Initial dose
Cyclophosphamide[a]	IV	0.75 g/m^2 q 3–4 weeks. Decrease initial dose to 0.5 g/m^2 if age >60 years or GFR <20 mL/minute/1.73 m^2. Adjust subsequent doses to achieve a 2-week nadir leukocyte count >3,000/mm^3.
Cyclophosphamide[b]	PO	1.5–2 mg/kg/day, reduce if age >60 years or GFR <20 mL/minute/1.73 m^2. Adjust the daily dose to keep leucocyte count >3,000/mm^3
Corticosteroids	IV	Pulse methylprednisolone: 500 mg i.v. daily × 3 days.
Corticosteroids	PO	Prednisone 1 mg/kg/day for 4 weeks, not exceeding 60 mg daily. Taper down over 3–4 months.
Rituximab[c]	IV	375 mg/m^2 weekly × 4.
Plasmapheresis[d]		60 mL/kg volume replacement. Vasculitis: 7 treatments over 14 days. If diffuse pulmonary hemorrhage, daily until the bleeding stops, then every other day, total 7–10 treatments. Vasculitis in association with anti-GBM antibodies: Daily for 14 days or until anti-GBM antibodies are undetectable

[a] Given with pulse and oral steroids. An alternative IV cyclophosphamide dosing schema is 15 mg/kg given every 2 weeks for three pulses, followed by 15 mg/kg given every 3 weeks for 3 months beyond remission, with reductions for age and estimated GFR.

[b] Given with pulse and oral steroids.

[c] Given with pulse and oral steroids.

[d] Not given with pulse methylprednisolone. Replacement fluid is 5% albumin. Add 150 to 300 mL fresh frozen plasma at the end of each pheresis session if patients have pulmonary hemorrhage, or have had recent surgery, including kidney biopsy.

ANCA, antineutrophil cytoplasmic antibody; GBM, glomerular basement membrane; GFR, glomerular filtration rate; GN, glomerulonephritis; IV, intravenous; PO, orally.

Corticosteroids

The main role of corticosteroids is to induce remission of the disease. J.M. should receive prednisone 1 mg/kg/day in addition to CYC. The combined regimen should be continued for 2 to 4 weeks until the immunosuppressive effect of CYC becomes evident. Then, during the next 2 months, the prednisone dose can be tapered to 60 mg every other day to reduce the risk of infection. Then, the dose can be tapered by 5 mg/week to discontinue prednisone over the course of 3 to 6 months. For patients with a more fulminant form of the disease, pulse methylprednisolone 500 mg/day for three doses is administered. The dose can be repeated in 1 to 2 weeks if disease progression is uncontrolled.

Alternative Therapies

Rituximab as an induction agent has been evaluated in two randomized controlled trials. The RITUXVAS randomized 44 subjects to rituximab (375 mg/m^2 weekly × 4) plus IV CYC or to IV CYC alone. Each group received IV methylprednisolone followed by oral corticosteroids. Remission rates were 76% for the rituximab group and 82% for CYC. The RAVE trial rituximab was compared to oral CYC (2 mg/kg/day) for up to 3 months plus AZA (2 mg/kg/day) for 4 to 6 months. IV methylprednisolone plus oral corticosteroid were given to both groups. Rituximab proved noninferior to the CYC regimen with similar rates, 64% versus 53%, respectively. There were no significant differences in adverse events rates in either trial. Although rituximab has performed well in comparison studies, the high cost limits it acceptance and applicability in clinical practice.

Azathioprine and Mycophenolate Mofetil

AZA (1–2 mg/kg/day) and MMF (up to 1 gram daily) are effective as maintenance therapy once remission has been achieved with CYC. However, a comparative study demonstrated mycophenolate to be less effective at maintaining remissions compared with AZA, thus AZA is the preferred maintenance therapy. [186] Maintenance therapy should be continued for a minimum of 18 months for patients in complete remission.

Alternative Agents

Methotrexate (MTX) may be beneficial for patients with milder disease, although one study demonstrated high relapse rates in patients treated initially with weekly MTX and daily prednisone; disease was controlled in only select patients.[187] However, MTX should be reserved for patients intolerant of AZA and MMF and GFR >60 mL/min/1.73 m^2. Use of trimethoprim-sulfamethoxazole for 1 year was evaluated for patients in remission or after treatment with CYC and prednisolone and is recommended for those with upper respiratory tract disease. A reduction in relapse rate was demonstrated compared with placebo; however, trimethoprim-sulfamethoxazole use is not supported.[187]

FOCAL SEGMENTAL GLOMERULOSCLEROSIS

CASE 28-6

QUESTION 1: A.G. is a 37-year-old morbidly obese (body mass index, 40 kg/m^2), black woman who presents to the clinic with complaints of increased swelling in her extremities for the last 2 weeks, decreased urine output, and pink-colored urine. Her medical history is significant only for hypertension, which is well controlled with amlodipine 5 mg PO every day. She takes no other prescription or over-the-counter medications. Pertinent laboratory values are as follows

SCr, 2.1 mg/dL (normal, 0.6–1.2 mg/dL)
Spot ACR, 1,200 mg/g (normal, <30 mg/g)
UA, 18 RBCs/HPF (normal, 0–3)
eGFR, 34 mL/minute/1.73 m^2

The nephrologist schedules a biopsy to obtain a definitive diagnosis for her new-onset kidney disease. Biopsy results are as follows: light micrograph shows a moderately large segmental area of sclerosis with capillary collapse on the upper left side of the glomerular tuft; the lower right segment is relatively normal. Electron micrograph shows diffuse epithelial cell foot process fusion with occasional loss of the epithelial cells. The other major finding is massive subendothelial hyaline deposits under the glomerular basement membrane. The pathologist's impression is FSGS. What is the relevance of FSGS, and what are the management strategies for FSGS?

FSGS is characterized by sclerotic lesions of the glomerulus, which can be either focal or segmental in nature. The development of FSGS may be idiopathic (primary) or secondary to other diseases (i.e., morbid obesity, sickle cell disease, congenital heart disease, AIDS). Currently, FSGS is the leading cause of idiopathic nephrotic syndrome and accounts for 15% to 20% of the cases. Black patients are 2 to 4 times more likely to experience idiopathic FSGS than white patients, and they have a higher incidence of ESRD caused by FSGS.[188] Genetic variants of the apolipoprotein L1 (APOL1) gene predominate in patients of African ancestry and have been identified as a major risk factor.[189]

Most patients with FSGS will present with proteinuria, but only about half of them will initially present with the nephrotic syndrome. Patients with the nephrotic syndrome will also likely present with hypertension, increased SCr levels, and hematuria. During the early stages of FSGS, the symptoms may be indistinguishable from minimal-change nephropathy, a glomerulopathy characterized by similar lesions within the glomeruli. A kidney biopsy is necessary for diagnosis. Predictors of increased risk of progression to ESRD include massive proteinuria (>10 g/day), higher SCr level (>1.3 mg/dL), and black race.[188,190]

Treatment

Corticosteroids

A.G. should be placed on steroids, in addition to an ACEI or ARB and a loop diuretic, because she has FSGS and nephrotic syndrome.[177] A course of corticosteroids 1 mg/kg/day (maximum 80 mg) or 2 mg/kg every other day (maximum 120 mg) for at least 4 weeks and for up to 4 months with tapering of the dose over the course of 6 months after complete remission is achieved. Complete remission is defined as reduction of albuminuria <0.3 g/day, normal urine and SCr, and serum albumin >3.5 g/dL.[177] The median time to remission is 3 to 4 months. Patients whose proteinuria does not respond after a 4-month trial of therapy should be considered resistant to steroids and be rapidly tapered off over the course of 6 weeks.[177]

Steroid-Resistant Treatment

Calcineurin Inhibitors

The addition of cytotoxic agents (CYC, TAC) may be considered for A.G. if she is steroid resistant, intolerant of long-term steroid therapy, severely nephrotic, frequently relapsing, or steroid dependent. The data supporting the use of these agents in FSGS are limited. Retrospective studies have shown that use of cytotoxic drugs can produce complete remission in 50% of cases. Length of therapy of these agents may predict the remission rates of FSGS. Recent prospective studies support a longer duration of therapy.

Evidence supporting the efficacy and safety of cyclosporine in FSGS stems from randomized controlled trials. In addition to being options for steroid-resistant patients, CNIs provide a steroid-sparing effect in FSGS steroid-sensitive patients. Cyclosporine studies are the most prevalent of the CNIs. Cyclosporine response is highly dependent on the previous steroid response. Complete remission rates of 73% can be seen with cyclosporine in steroid-sensitive patients.[190] Conversely, therapy with cyclosporine doses of 5 mg/kg/day for 6 to 12 months has been found to be effective and can result in remission rates of up to 69% in patients resistant to steroids.[191] The current recommendation is CYC of 3 to 5 mg/kg/day in two divided doses. If remission is achieved, continue treatment for 1 year. However, if no remission is achieved by 6 months, discontinue cyclosporine. Limitations of cyclosporine therapy include high relapse rate (23%–100%) after withdrawal, side effect profile (nephrotoxicity, hypertension), and resistance to therapy. Studies evaluating tacrolimus as a treatment option for FSGS are few and lack randomized controlled trials. Current TAC therapy should be initiated at 0.1 to 0.2 mg/kg/day in two divided doses. Tacrolimus has a similar side effect profile to that of cyclosporine.[190] Sirolimus is associated with nephrotoxicity in FSGS and is not recommended for treatment.

Mycophenolate Mofetil

MMF has the potential for a steroid-sparing effect; however, relapses are common. MMF and high-dose dexamethasone are recommended for steroid-resistant patients intolerant to cyclosporine therapy. A small study of patients with FSGS resistant to steroids, cytotoxic agents, or both and cyclosporine received MMF for 6 months.[177]

At the end of 6 months, 44% of patients had improved proteinuria, but no patient achieved complete remission. Other studies examining MMF therapy at doses of up to 2,000 mg/day have found no clinically significant effect on remission rates.[192]

Acute Kidney Injury

Susan A. Krikorian and Oussayma Moukhachen

CORE PRINCIPLES		CHAPTER CASES
1	Acute kidney injury (AKI) is characterized clinically by an abrupt decrease in renal function over a period of hours to days, resulting in the accumulation of nitrogenous waste products (azotemia) and the inability to maintain and regulate fluid, electrolyte, and acid–base balance.	**Case 29-1 (Question 1), Table 29-1**
2	Risk factors for the development of AKI include older age, higher baseline serum creatinine (SCr), chronic kidney disease (CKD), diabetes, chronic respiratory illness, underlying cardiovascular disease, prior heart surgery, dehydration resulting in oliguria, acute infection, and exposure to nephrotoxins.	**Case 29-1 (Question 1), Case 29-2 (Questions 1, 2), Case 29-3 (Questions 2, 4) Tables 29-5, 29-6, 29-7, 29-8 Case 29-5 (Question 2), Case 29-6 (Question 1)**
3	The clinical course of AKI has three distinct phases: the oliguric phase—a progressive decrease in urine production after kidney injury; the diuretic phase—initial repair of the kidney insult with resultant diuresis of accumulated uremic toxins, waste products, and fluid; and the recovery phase—return of kidney function depending on the severity of injury.	**Case 29-1 (Questions 1–3)**
4	AKI is classified according to the physiologic event leading to AKI: prerenal azotemia—decreased renal blood flow; functional—impairment of glomerular ultrafiltrate production or intraglomerular hydrostatic pressure; intrinsic—damage to the kidneys; and postrenal—outflow obstruction in the urinary tract.	**Case 29-1 (Questions 1, 2), Case 29-2 (Question 1, 4), Case 29-3 (Question 1), Case 29-5 (Question 1), Case 29-6 (Question 1), Case 29-7 (Question 1), Case 29-8 (Question 1), Table 29-2**
5	The urinalysis is an important diagnostic tool for differentiating AKI into prerenal azotemia, intrinsic, or obstructive AKI. Urinary chemistries are used to differentiate between prerenal azotemia and intrinsic AKI.	**Case 29-1 (Question 2), Case 29-3 (Question 1), Case 29-6 (Question 1), Case 29-7 (Question 1), Case 29-8 (Question 1), Tables 29-3, 29-4, Equation 29-1**
6	Medications that affect renal function (e.g., angiotensin-converting enzyme [ACE] inhibitors, angiotensin II receptor blockers [ARBs], and aminoglycoside antibiotics) should be dosed according to renal function	**Case 29-1 (Question 3), Case 29-2 (Question 1, 4), Case 29-3 (Question 5),**

and monitored closely in patients with AKI. Nephrotoxic medications should be avoided.	**Case 29-6 (Question 2, 3), Case 29-9 (Question 1)**
⑦ Patients with nonoliguric renal failure have significantly better outcomes than those with oliguria; however, converting a patient from oliguria to nonoliguria through pharmacologic intervention does not improve patient outcomes.	**Case 29-9 (Question 1)**
⑧ Hydration therapy is useful in the following ways: to increase renal perfusion and avert the conversion of prerenal azotemia to acute tubular necrosis (ATN), to reduce the risk of contrast-induced nephropathy (CIN) in high-risk patients, and to prevent and treat kidney stones.	**Case 29-2 (Question 3), Case 29-5 (Question 3), Case 29-8 (Question 1), Case 29-9 (Question 1), Table 29-5**

⑨ Few treatment options are available in established AKI, therefore prevention is key. Supportive therapy is aimed at preventing the morbidity and mortality of AKI: close patient monitoring; strict fluid, electrolyte, and nutritional management; treatment of life-threatening conditions, such as pulmonary edema, hyperkalemia, and metabolic acidosis; avoidance of nephrotoxic drugs; and initiation of renal replacement therapy (RRT).	**Case 29-1 (Question 3), Case 29-5 (Question 4), Case 29-7 (Question 2), Case 29-9 (Question 1)**
⑩ Although diuretics have not been shown to improve patient outcomes, they can be used to prevent complications from fluid overload. Sodium restriction, daily monitoring of volume status, laboratory chemistries, urine output, and gastrointestinal (GI) and insensible losses should be measured during diuretic therapy.	**Case 29-1 (Question 3), Case 29-3 (Question 3), Case 29-4 (Question 1), Case 29-9 (Question 1)**
⑪ RRT is reserved for patients with severe acid–base disorders, fluid overload, hyperkalemia, or symptomatic uremia as a result of AKI. Dosage adjustments are necessary for drugs that are removed during RRT.	**Case 29-9 (Question 2), Table 29-9**

DEFINITION

Acute kidney injury (AKI) is characterized clinically by an abrupt decrease in renal function over a period of hours to days, resulting in the accumulation of nitrogenous waste products, urea and creatinine (azotemia), and the inability to maintain and regulate fluid, electrolyte, and acid–base balance.[1] AKI is a devastating syndrome with multiple risk factors or causes. It is associated with multi-organ dysfunction, increased resource utilization, high cost, and increased mortality. Like chronic kidney disease (CKD), AKI is common, treatable, and is also largely preventable. Not only is underlying CKD a risk factor for AKI, but AKI also contributes to CKD development and may result in dialysis dependency. Minimizing causes of AKI and increasing awareness of the importance of early detection and treatment are associated with improved outcome in AKI. Clinicians recognize a rapid approach to treatment is essential because the causes and complications of AKI do not allow much time to initiate management and reversal.[2–6]

Many attempts have been made to objectively quantify AKI based on laboratory data, daily urine output, or the need for renal replacement therapy (RRT) (i.e., dialysis). Over the past decade the working definition of AKI has evolved. Currently, expert opinion and consensus recommend assessing quantitative serum creatinine (SCr) changes from baseline or urinary volume. They are considered important clinical pointers in the detection, diagnosis, and severity of AKI. Vigilant daily assessment of these markers continues while the patient is hospitalized. In 2004, the Acute Dialysis Quality Initiative created an international expert panel, which proposed a new classification system called RIFLE.[7] This system defines various stages of AKI, including risk, injury, failure, loss (defined as the need for dialysis at least 1 month after failure), and finally end-stage renal disease (ESRD). In 2007, the recognition that even smaller changes in SCr than defined in RIFLE might be associated with adverse outcomes and mortality led to newer definitions by the Acute Kidney Injury Network (AKIN).[8] The three AKIN stages map to, but are not identical to, the RIFLE classification. The RIFLE and AKIN are very useful for quantitating renal function for research purposes rather than clinical activities. In 2012, the Kidney Disease Improving Global Outcomes (KDIGO)[9] guidelines proposed a uniform practical clinical definition of AKI, essentially merging the RIFLE and AKIN criteria. AKI is defined as an increase in SCr > 0.3 mg/dL within 48 hours, OR an increase in SCr > 1.5 times baseline in 7 days or less OR a decrease in urine volume <0.5 mL/kg/hour for >6 hours. The most recent guideline provides a useful tool to assist clinicians for managing AKI (Table 29-1).

These new classification systems provide advantages over traditional definitions, and represent a significant step forward in detecting and preventing AKI. Future studies need to prospectively evaluate their application in diverse clinical settings on the basis of evidence rather than opinion or consensus and also their performance as prognostic predictors of patient outcome. Regardless of the definitions used, the clinician should suspect AKI when the kidney is unable to regulate fluid, electrolyte, acid–base, or nitrogen balance, even in the presence of a normal SCr concentration. Healthcare technology information systems are working on alerts to notify clinicians to warn of possible AKI during patient care.[3,10]

EPIDEMIOLOGY

Multivariable models have identified risk factors for the development of AKI, including older age, higher baseline SCr, underlying CKD, diabetes, chronic respiratory illness, underlying cardiovascular disease, prior heart surgery, dehydration resulting in oliguria, acute infection, and exposure to nephrotoxins.[11] The incidence of community-acquired AKI (development of AKI before hospitalization) is just 1%; approximately 75% of these admissions result from decreased kidney blood flow, termed prerenal azotemia. Other less-common causes include obstructive uropathy (17%) and intrinsic renal disease (11%).[12] Community-acquired AKI can usually be reversed by correcting the underlying problems of volume status or obstruction. Hospital-acquired AKI is much more common, and the incidence and severity vary based on intensive care unit (ICU) or non-ICU setting.[13] The incidence of AKI in general-medicine patients is approximately 5% to 7%, with the most common causes being prerenal azotemia, postoperative complications, or nephrotoxin exposure.[14,15] These patients can experience one or more of these renal insults throughout their hospitalization. Conversely, ICU-acquired AKI is more prevalent and severe. Data suggest the incidence of AKI in patients in the ICU approaches 25%, stemming from multiple risk factors including older age, sepsis, nephrotoxin exposure, male sex (gender), multi-organ dysfunction, and the need for mechanical ventilation.[16–18] Severe burns, rhabdomyolysis, chemotherapy, and open heart surgery are also considered risk factors. The natural history of patients who develop AKI includes (1) complete recovery of renal function, (2) development of progressive CKD, (3) increased rate of progression of preexisting CKD, or (4) irreversible loss of kidney function with dialysis-dependent ESRD.[19] Although many patients with stage 3 AKI will initially require dialysis, a small percentage will develop ESRD requiring long-term dialysis.

Table 29.1

Classification/Staging System for Acute Kidney Injury

Category	SCr and GFR Criteria	Urine Output Criteria
RIFLE Criteria		
Risk	Increased SCr × 1.5-fold or GFR decrease >25%	<0.5 mL/kg/hour × 6 hour
Injury	Increased SCr × 2-fold or GFR decrease >50%	<0.5 mL/kg/hour × 12 hour
Failure	Increased SCr × 3-fold or GFR decrease >75% or SCr ≥4.0 mg/dL with an acute increase of at least 0.5 mg/dL	<0.3 mL/kg/hour × 24 hour or anuria × 12 hour
Loss	Complete loss of kidney function (RRT) >4 weeks	
ESRD	RRT >3 months	
AKIN Criteria		
Stage 1	Increased SCr ≥0.3 mg/dL or × ≥1.5 to 2-fold	<0.5 mL/kg/hour × >6 hour
Stage 2	Increased SCr × >2 to 3-fold	<0.5 mL/kg/hour × >12 hour

Stage 3	Increased SCr × >3-fold or SCr ≥4 mg/dL with an acute increase of at least 0.5 mg/dL or need for RRT	<0.3 mL/kg/hour × 24 hour or anuria × 12 hour
KDIGO Criteria		
Stage 1	Increased SCr ≥0.3 mg/dL within 48 hours or increased SCr × 1.5 to 1.9-fold in 7 days or less	<0.5 mL/kg/hour × 6–12 hour
Stage 2	Increased SCr × 2 to 2.9-fold	<0.5 mL/kg/hour × ≥12 hour
Stage 3	Increased SCr × ≥3-fold or SCr ≥4 mg/dL or need for RRT or eGFR <35 mL/minute/1.73 m^2	<0.3 mL/kg/hour × ≥24 hour or anuria × ≥12 hour

SCr, serum creatinine; GFR, glomerular filtration rate.

PROGNOSIS

Despite recent advances in dialysis delivery and the development of sophisticated continuous renal replacement therapy (CRRT), patients with AKI continue to have a grim prognosis. A mild elevation of SCr in ICU patients is associated with a twofold increase in the risk of death.[20] Indeed, the occurrence of AKI in critically ill patients carries at least a 50% mortality rate. Worse yet, the mortality rate increases correspondingly by 10% with each additional failed organ system. The mortality rate of AKI has declined minimally during the last 50 years. This slow decline may be explained in part by three important factors. First, patients are older when they develop AKI. Second, patients are often afflicted with serious underlying medical illnesses beyond AKI. Third, the clinical severity status of the patient with AKI is much higher now than ever before. Before the widespread availability of RRT, the most common causes of death in patients with AKI were fluid and electrolyte disorders and advanced uremia. Today, the most common causes of death are sepsis, cardiovascular disease as a result of heart failure and ischemic heart disease, malignancy, and withdrawal of life support.[21]

CLINICAL COURSE

There are three distinct phases of AKI. The oliguric phase generally occurs over the course of 1 to 2 days and is characterized by a progressive decrease in urine production. Urine production of less than 400 mL/day is termed oliguria, and urine production of less than 50 mL/day is termed anuria. The oliguric stage may last from days to several weeks. Nonoliguric renal failure (>400 mL/day of urine output) carries a better prognosis compared with oliguric renal failure, although the exact reason remains unknown. Similarly, the shorter the duration of oliguria, the higher the likelihood of successful recovery. This is probably because the renal insults (e.g., dehydration, nephrotoxin exposure, postrenal obstruction) in these cases are less severe. Strict fluid and electrolyte monitoring and management are required during this phase until renal function normalizes.

After the oliguric phase, a period of increased urine production occurs for several days; this is called the diuretic phase. This phase signals the initial repair of the kidney insult. The diuretic phase can result, in part, from a return to normal glomerular filtration rate (GFR) before tubular reabsorptive capacity has fully recovered. The elevated osmotic load from uremic toxins and the increased fluid volume retained during the oliguric phase may also contribute to the diuretic phase. Despite the increased urine production, patients may remain markedly azotemic for several days. The increase in urine output may lead to volume depletion and electrolyte loss if patients are not given adequate replacement therapy. Daily modifications in the fluid and electrolyte requirements are necessary based on urine output.

The recovery phase occurs over the course of several weeks to months, depending on the severity of the patient's AKI. This phase signals the return to the patient's baseline kidney function, normalization of urine production, and the return of the diluting and concentrating abilities of the kidneys.

PATHOGENESIS

The production and elimination of urine requires three basic physiologic events:

- Blood flow to the glomeruli
- The formation and processing of ultrafiltrate by the glomeruli and tubular cells
- Urine excretion through the ureters, bladder, and urethra

Many conditions and drugs can alter these physiologic events leading to AKI. These are classified as prerenal azotemia, and functional, intrinsic, and postrenal AKI (Table 29-2). It is possible for more than one of these categories to coexist.[22,23]

Normal renal function depends on adequate renal perfusion. The kidneys receive up to 25% of cardiac output, which is greater than 1 L/minute of blood flow. Prerenal azotemia, the most common form of AKI, occurs when blood flow to the kidneys is reduced. Major causes include decreased intravascular volume (e.g., hemorrhage or dehydration [including overdiuresis]), decreased effective circulating volume states (e.g., cirrhosis or heart failure [HF]), hypotensive events (e.g., shock or medication-related hypotension), and renovascular occlusion or vasoconstriction. Because no structural damage occurs to the kidney parenchyma per se, correcting the underlying cause rapidly restores GFR. Sustained prerenal conditions can result, however, in glomerular ischemia causing acute tubular necrosis (ATN).

Table 29-2

Causes of Acute Kidney Injury

Classification	Common Clinical Disorders
Prerenal azotemia	**Intravascular Volume Depletion**
	Hemorrhage (surgery, trauma) Dehydration (gastrointestinal losses, aggressive diuretic administration) Severe burns Hypovolemic shock Sequestration (peritonitis, pancreatitis)
	Decreased Effective Circulating Volume
	Cirrhosis with ascites Heart failure
	Hypotension, Shock Syndromes
	Antihypertensive vasodilating medications Septic shock Cardiomyopathy
	Increased Renal Vascular Occlusion or Constriction
	Bilateral renal artery stenosis Unilateral renal stenosis in solitary kidney Renal artery or vein thrombosis (embolism, atherosclerosis) Vasopressor medications (phenylephrine, norepinephrine)
Functional acute kidney injury	**Afferent Arteriole Vasoconstrictors**
	Cyclosporine Nonsteroidal anti-inflammatory drugs
	Efferent Arteriole Vasodilators
	Angiotensin-converting enzyme inhibitors Angiotensin II receptor antagonists
Intrinsic acute kidney injury	**Glomerular Disorders**

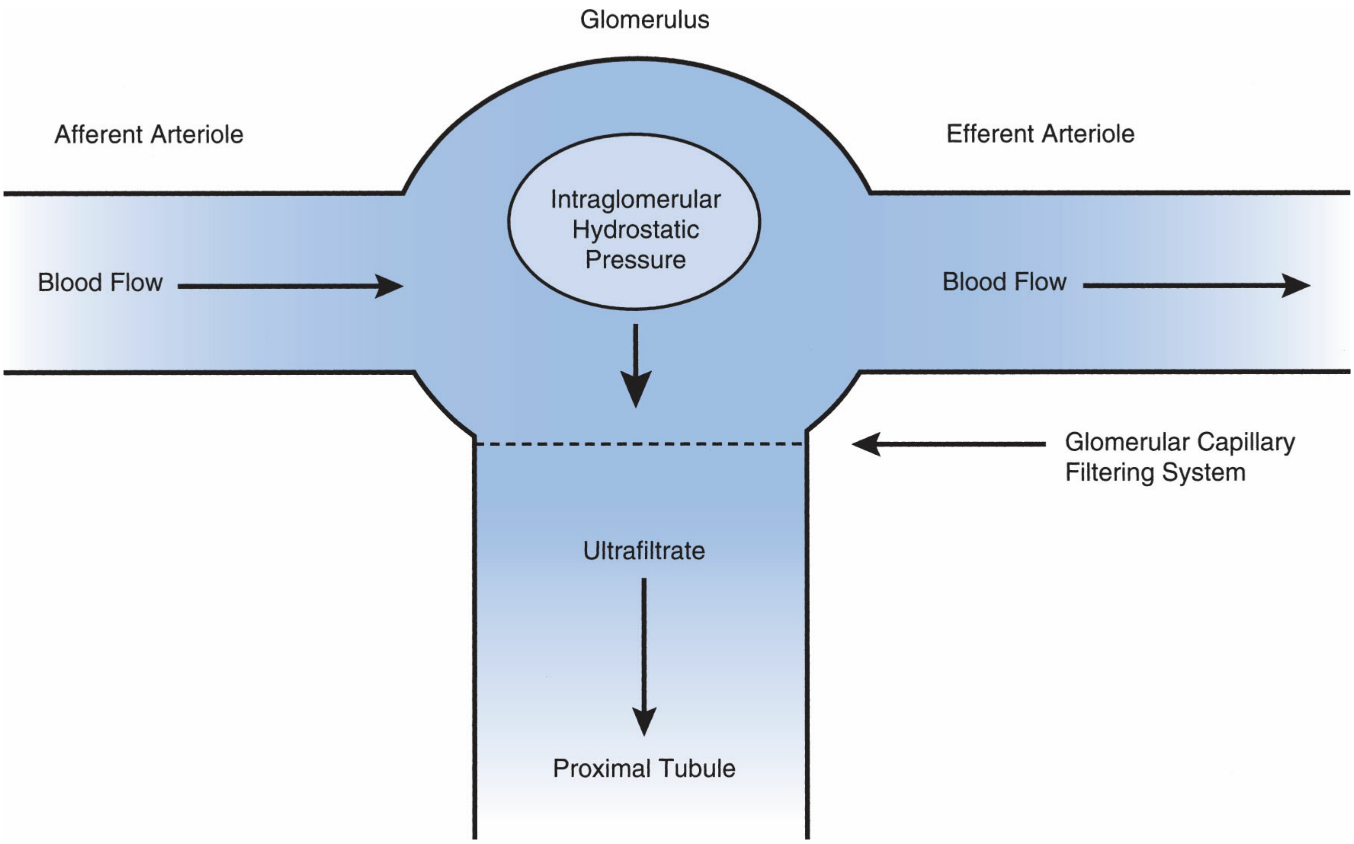

Figure 29-1 Schematic of renal blood flow. Blood enters the glomerulus via the afferent arteriole. The intraglomerular hydrostatic pressure leads to ultrafiltration across the glomerulus into the proximal tubule. The unfiltered blood leaves the glomerulus via the efferent arteriole. In conditions of decreased renal perfusion, efferent arteriolar vasoconstriction occurs to increase intraglomerular hydrostatic pressure and maintain ultrafiltrate production. Afferent arteriolar vasodilation also occurs to improve blood flow into the glomerulus.

Functional AKI results when medical conditions or drugs impair glomerular ultrafiltrate production or intraglomerular hydrostatic pressure as a result of impaired autoregulation. Blood travels through the afferent arteriole and enters the glomerulus, where it is filtered, and exits through the efferent arteriole (Fig. 29-1). The afferent and efferent arterioles work in concert to maintain adequate glomerular capillary hydrostatic pressure to form ultrafiltrate. Many medications can drastically reduce intraglomerular hydrostatic pressure and GFR by producing afferent arteriolar vasoconstriction or efferent arteriolar vasodilation (Fig. 29-2).

Intrinsic AKI can occur at the microvascular level of the nephron, glomeruli, renal tubules, or interstitium. Vasculitic diseases (e.g., Wegener's granulomatosis, cryoglobulinemic vasculitis) involve the small vessels of the kidney. Glomerulonephritis and systemic lupus erythematosus, although relatively uncommon, result in glomerular damage. ATN is by far the most common cause of intrinsic AKI. In fact, the term acute tubular necrosis is often used interchangeably with AKI. ATN occurs in part because the renal tubules require high oxygen delivery to maintain their metabolic activity. Consequently, any condition that causes ischemia to the tubules (e.g., hypotension, decreased blood flow) can induce ATN. Moreover, the tubules may be exposed to exceedingly high concentrations of nephrotoxic drugs (e.g., aminoglycosides). Interstitial nephritis or inflammation within the renal parenchyma is most often associated with drug administration (e.g., penicillins).

Postrenal AKI occurs when there is an outflow obstruction in the upper or lower urinary tract. Lower tract obstruction is most common and can be caused by prostatic hypertrophy, prostate or cervical cancer, anticholinergic drugs that cause bladder sphincter spasm, or renal calculi. Upper tract obstruction is less common and occurs when both ureters are obstructed or when one is obstructed in a patient with a single functioning kidney. Postrenal AKI usually resolves rapidly after the obstruction has been removed. Postobstructive diuresis can be dramatic (e.g., 3–5 L/day).[23]

CLINICAL EVALUATION

History and Physical Examination

A detailed history and physical examination often reveal the cause(s) of AKI. The clinician’s responsibility is to ask specific, open-ended questions regarding the patient’s chief complaint; history of present illness; medical history; family, social, and allergy history; and current prescription and nonprescription medication use. Probing for pertinent information regarding recent surgery, nephrotoxin exposure, or concurrent medical conditions can aid in rapidly determining the etiology of AKI. For example, does the patient have preexisting conditions that point toward prerenal azotemia, such as heart failure (HF) or liver disease? Did the patient receive prophylactic antibiotics before surgery? Did the patient hemorrhage or have protracted hypotension during surgery? Furthermore, assessment of the vital sign flowchart for documented weight loss, hypotensive events, fluid intake, and urine output may also prove useful.

A thorough physical examination, when used in conjunction with the history, can be invaluable in confirming the cause of AKI. The patient’s volume status should be evaluated first. Evidence of dehydration (e.g., syncope, weight loss, orthostatic hypotension) or decreased effective circulating volume (e.g., ascites, pulmonary edema, peripheral edema, jugular venous distension) usually indicates prerenal azotemia. The presence of edema in a patient with normal cardiac function can, however, signal the early signs of nephrotic syndrome. A more detailed discussion of nephrotic syndrome is presented in Chapter 28, Chronic Kidney Disease. Concurrent rash and AKI associated with recent antibiotic exposure suggest drug-induced allergic interstitial nephritis. The clinician should suspect rhabdomyolysis in a patient with trauma or crush injuries and AKI. In a patient with suspected AKI the purpose of ultrasonography early in the diagnostic work-up is to rule out obstructive causes of oliguria. An enlarged prostate, painful urination, or wide deviations in urine volume can suggest obstructive AKI causes. Flank and lower abdominal pain suggest upper obstruction, whereas urinary frequency, hesitancy, dribbling, and abdominal fullness indicate lower obstruction.

Laboratory Evaluation

QUANTIFYING GLOMERULAR FILTRATION RATE

No estimating equations can provide an accurate estimate of GFR in AKI because the SCr is fluctuating and not at steady-state. In Chapter 28, Chronic Kidney Disease, the Modification of Diet in Renal Disease (MDRD) equation and the Cockcroft–Gault (CG) equation are reviewed, and both require a SCr value at steady-state. The MDRD equation is used to quantify baseline GFR, to detect or stage the degree of CKD, and to follow progression. The CG equation is most commonly used to evaluate the appropriate doses of drugs that are eliminated by the kidney.[9] CG may significantly overestimate the renal function in the early stages of AKI and may underestimate the renal function when AKI is resolving.[24] An example of this is a patient who develops ATN and anuria. Within the first few days, the SCr level may increase slightly because it takes time for the SCr concentration to achieve a new steady-state. In fact, the calculated creatinine clearance (ClCr) may even remain in the normal range, although the true GFR is substantially lower. The converse is true with patients recovering from ATN. As the diuretic phase of ATN begins, urine output can be dramatic, but patients may remain markedly azotemic for several days. Using the CG equation in this setting will produce a falsely low ClCr estimate. The CG equation is also inaccurate in populations that have low muscle mass—such as elderly, obese, or cachectic patients. Use of SCr to assess kidney function in patients with liver disease may also lead to overestimation of GFR.[25] This may be attributed to decreased production of creatine (the precursor of creatinine) by the liver or increased tubular secretion of creatinine by the kidney. Therefore, clinicians should be aware that estimating equations have potential limitations and pitfalls. In the past, many clinicians advocated the collection of timed urine specimens to calculate ClCr in AKI. Although this may seem relatively simple, it is susceptible to serious errors, particularly the timing of the collection and ensuring that the patient has not voided urine in the commode, resulting in an incomplete urine collection. For these reasons, the practice of collecting timed urine specimens is no longer routinely performed. Populations in whom estimation of GFR using a 24-hour urine collection is more reasonable include patients with variation in dietary intake of creatine sources (such as vegetarians) or persons with poor muscle mass (e.g., malnourished individuals or amputees).[26] Alternatively, shorter collection times or spot untimed urine samples are sometimes used to determine creatinine excretion.

Because an acute decline in kidney function may not be reflected by a rise in SCr for several hours, the recent emergence of novel serum and/or urinary AKI biomarkers is expected to aid in the early diagnosis of AKI. Neutrophil gelatinase-associated lipocalin (NGAL), Kidney Injury Molecule-1 (KIM-1), interleukin-18 (IL-18), and cystatin C have been shown to detect AKI in different patient cohorts. Future clinical trials are needed to identify and validate their prognostic role in AKI and estimating GFR.[27–31]

Many drugs are eliminated at least in part by the kidneys and must be dosed according to renal function. A more detailed discussion of drug dosing in the presence of compromised renal function is provided in Chapter 31, Dosing of Drugs in Renal Failure. Thus, standard doses and dosing intervals of many agents in the presence of AKI may lead to increased drug exposure of the active drug or metabolites. It is important to recommend appropriate drug doses in the presence of AKI. Some clinicians make renal dosing recommendations based on eGFR <15 mL/minute as an initial guide for drug therapy in an AKI patient not receiving CRRT when no other information is available. Drugs not essential for care should be discontinued to avoid potential drug-induced toxicity in the presence of AKI.

Careful monitoring of clinical and biochemical surrogate parameters associated with efficacy and toxicity and therapeutic drug monitoring (TDM), especially for drugs with a narrow therapeutic index eliminated by the kidneys, are required. High-risk medications such as aminoglycosides, vancomycin and calcineurin inhibitors (e.g., cyclosporine, tacrolimus), those with known nephrotoxicity, or other potential toxicities associated with supratherapeutic serum concentrations should be closely monitored. It is also important to note the volume of distribution (Vd) of drugs such as aminoglycosides, vancomycin, β-lactams (e.g., most cephalosporins, carbapenems) is dramatically increased in the presence of AKI. Therefore, larger loading doses may need to be administered to avoid subtherapeutic responses from lower than desired serum concentrations.[32–34] For most drugs, clinically useful serum drug assays are unavailable. Therefore, trends in renal function indices (e.g., SCr and urine output) along with volume status and response to therapy should be utilized to guide drug dosing. Further dose adjustments may be necessary when RRT is provided.

BLOOD TESTS

Assessment of blood urea nitrogen (BUN) and SCr concentrations is crucial for guiding the diagnosis, treatment, and monitoring of AKI. Measurement of BUN is discussed in Chapter 2, Interpretation of Clinical Laboratory Tests. The BUN:SCr ratio can delineate prerenal causes from intrinsic and postrenal causes. Urea reabsorption is inversely proportional to the urine flow rate. The normal steady-state BUN:SCr ratio is approximately 10:1. In prerenal conditions, the BUN:SCr ratio is greater than 20:1 because sodium and water are actively reabsorbed in the renal tubules to expand the effective circulating volume. Urea, an ineffective osmole, is reabsorbed as a result of increased water reabsorption, whereas creatinine is not reabsorbed. Although SCr may increase owing to decreased glomerular filtration, BUN increases to a greater degree as a result of increased proximal reabsorption.

The presence of hypercalcemia or hyperuricemia can indicate a hematologic malignancy. Tumor lysis syndrome is a condition that occurs in patients with leukemia after chemotherapy induction. The destruction of cancerous cells results in the release of large quantities of cellular contents (e.g., potassium, uric acid) into the bloodstream, which can overwhelm the kidney’s functional ability, especially in dehydrated states.

Other elevated enzymes may also aid in the diagnosis of AKI. An increased level of creatine kinase or myoglobin in the face of AKI usually indicates rhabdomyolysis. Eosinophilia may suggest acute allergic interstitial nephritis from drug exposure. High levels of circulating immune complexes in the presence of AKI suggest glomerulopathies.[22]

URINALYSIS

The urinalysis is an important diagnostic tool for differentiating AKI into prerenal azotemia, intrinsic AKI, or obstructive AKI (Table 29-3). The presence of highly concentrated urine, as determined by elevated urine osmolality and specific gravity, suggests prerenal azotemia. During dehydrated states, vasopressin (antidiuretic hormone) is secreted, and the renin–angiotensin–aldosterone system (RAAS) is activated. These mechanisms promote the reabsorption of water and sodium at the collecting duct of the nephron, which serves to expand the effective circulating volume in an attempt to restore renal perfusion. As a result of diminished urine volume, the urine osmolality and specific gravity increase dramatically. Patients with prerenal azotemia and oliguria often have a urine osmolality greater than 500 mOsm/kg. The maximal urine osmolality can exceed 1,200 mOsm/kg.

Table 29-3

Urinary Indices in Acute Kidney Injury

Component	Prerenal Azotemia	Acute Tubular Necrosis	Postrenal Obstruction
Urine Na+ (mEq/L)	<20	>40	>40
FE_{Na} (%)	<1	>2	>1
Urine/plasma creatinine	>40	<20	<20
Specific gravity	>1.010	<1.010	Variable
Urine osmolality (mOsm/kg)	Up to 1,200	<300	<300

The presence of proteinuria or hematuria can indicate glomerular damage. Nephrotic syndrome is characterized by urinary protein losses greater than 3.5 g/1.73 m^2/day. Proteinuria can also result from tubular damage; that protein loss is rarely over 2 g/day, however. The protein content can be used to differentiate glomerular versus tubular damage. The low-molecular-weight protein, β_2-microglobulin, is freely filtered at the glomerulus and reabsorbed at the proximal tubule. Therefore, the presence of excessive β_2-microglobulin in the urine suggests a tubular source of AKI, such as ATN. Conversely, albumin is not readily filtered at the glomerulus; hence, the presence of heavy albuminuria suggests a glomerular source of AKI.

Microscopic examination of the urine provides helpful clues for determining the source of AKI (Table 29-4). Pigmented granular casts are generally seen with ischemic or nephrotoxin-induced AKI. White blood cells (WBCs) and WBC casts can indicate an inflammatory process in the glomerulus, such as acute interstitial nephritis (AIN) or pyelonephritis. Red blood cells (RBCs) and RBC casts can result from strenuous exercise or can indicate glomerulonephritis. Allergic interstitial nephritis can be detected by the presence of urinary eosinophils. Obstructive AKI causes, such as nephrolithiasis, can be identified by the presence of crystals in the urine. Cystine, leucine, and tyrosine crystals are considered pathologic. The presence of calcium oxalate crystals may suggest toxic ingestion of ethylene glycol.

Table 29-4

Clinical Significance of Urinary Sediment in Acute Kidney Injury

Cellular Debris	**Clinical Significance**
Red blood cells	Glomerulonephritis IgA nephropathy Lupus nephritis
White blood cells	Infection (pyelonephritis) Interstitial nephritis Glomerulonephritis Acute tubular necrosis
Eosinophils	Drug-induced acute interstitial nephritis Pyelonephritis Renal transplant rejection
Hyaline casts	Glomerulonephritis Pyelonephritis Heart failure
Red blood cell casts	Acute tubular necrosis Glomerulonephritis Interstitial nephritis
White blood cell casts	Pyelonephritis Interstitial nephritis
Granular casts	Dehydration Interstitial nephritis Glomerulonephritis Acute tubular necrosis
Tubular cell casts	Acute tubular necrosis
Fatty casts	Nephrotic syndrome
Myoglobin	Rhabdomyolysis
Crystals	Nonspecific

Note: Hyaline casts may also be detected in normal renal function.

URINARY CHEMISTRIES

Analyzing urine electrolyte concentrations and simultaneously comparing them with serum sodium and creatinine concentrations is useful for differentiating between prerenal azotemia and ATN (Table 29-3). The fractional excretion of sodium (FE_{Na}) is a measurement of how actively the kidney is reabsorbing sodium, and it is calculated as the fraction of filtered sodium excreted in the urine using creatinine as a measure of GFR. In normal conditions, the proximal tubule reabsorbs 99% of filtered sodium. The FE_{Na} formula is listed as follows:

$$FE_{Na^+}\ (\%) = \frac{(U_{Na})(SCr)}{(U_{cr})(S_{Na})} \times 100\% \qquad \text{(Eq. 29-1)}$$

where U_{Na} is the urine sodium concentration (mEq/L), SCr is the serum creatinine concentration (mg/dL), U_{Cr} is the urine creatinine concentration (mg/dL), and S_{Na} is the serum sodium concentration (mEq/L).[35] In prerenal azotemia, the functional ability of the proximal renal tubule remains intact. In fact, its sodium-reabsorbing abilities are markedly enhanced because of the effects of circulating vasopressin and activation of the RAAS. Both the FE_{Na} and urine sodium concentration become markedly low (<1% and <20 mEq/L, respectively) in prerenal conditions. In contrast, these indices are elevated in ATN because the renal tubules lose their ability to reabsorb sodium; the FE_{Na} is greater than 2%, and the urine sodium is greater than 40 mEq/L. FE_{Na} values between 1% and 2% are generally inconclusive. The clinician should ensure that the patient is not receiving scheduled thiazide or loop diuretic therapy when the FE_{Na} is calculated. These diuretics increase natriuresis, thereby making the results difficult to interpret. Urea excretion is not affected by diuretics. The FE_{Urea} appears more accurate in detecting prerenal azotemia, particularly in patients taking diuretics. Serum and urine creatinine concentrations are replaced by blood and urine urea concentrations in the FE_{Na} formula. A FE_{urea} of <35% and >50% are used to distinguish prerenal azotemia and ATN, respectively.[36]

PRERENAL AND FUNCTIONAL ACUTE KIDNEY INJURY

Chronic Heart Failure and Nonsteroidal Anti-Inflammatory Drug Use

CASE 29-1

QUESTION 1: A.W. is a 71-year-old white male (height = 6 feet; weight = 194 pounds), who had an ST-segment elevation myocardial infarction (STEMI) 2 months ago. His ejection fraction is currently 15% (normal, 50%–60%). He presents today for his 2-month follow-up clinic appointment complaining of shortness of breath, dyspnea on exertion, and inability to produce much urine. His medical history is significant for long-standing hypertension, coronary artery disease, osteoarthritis, and recent-onset HF after his MI. His home medications include furosemide 40 mg daily, lisinopril 20 mg daily, metoprolol succinate 100 mg daily, digoxin 0.125 mg daily, atorvastatin 40 mg daily, and naproxen sodium 550 mg twice daily (BID), all of which are taken orally (PO). With the exception of naproxen, A.W. often forgets to take his medications. Physical examination reveals lower leg 3+ pitting edema, pulmonary crackles and wheezes, positive jugular venous distension, and an S_3 heart sound. His vital signs are significant for a blood pressure (BP) of 198/97 mm Hg and a weight gain of 4 kg since his last visit 2 months ago. Last week, his BUN and SCr were 23 and 1.2 mg/dL, respectively. What are A.W.'s risk factors for AKI?

A.W.'s risk factors for AKI are heart failure (HF) with poor cardiac output (ejection fraction, 15%) that resulted from his STEMI and his medication, naproxen sodium. HF is a major cause of functional AKI.[37] A.W.'s diminished cardiac output has resulted in decreased effective circulating volume and activation of the RAAS, which are impairing his renal perfusion. In states of decreased renal perfusion, prostaglandins E2 and I2 compensate for the afferent arteriole vasoconstriction by stimulating afferent arteriole vasodilation, thereby enhancing renal blood flow. Prostaglandin synthesis is mediated predominantly by cyclo-oxygenase-1 (COX-1) and perhaps cyclo-oxygenase-2 (COX-2). Nonsteroidal anti-inflammatory drugs (NSAIDs), such as naproxen, are often overlooked as causes of AKI. NSAIDs exert their pharmacologic effect by inhibiting prostaglandin synthesis, thereby negating compensatory vasodilation. NSAIDs induce abrupt decreases in GFR in at-risk patient populations, specifically those with HF, liver disease, the elderly, or dehydrated patients. Figure 29-2 illustrates common medications that alter renal hemodynamics by causing either afferent arteriole vasoconstriction or efferent arteriole vasodilation. The term "triple whammy" refers to the risk of AKI when an ACE inhibitor or ARB is combined with a diuretic and NSAID. This combination might be seen in a patient with hypertension, congestive heart failure, or renal disease who has arthritis or other mild-to-moderate pain.[38,39]

COX-2 inhibitors also inhibit prostaglandin synthesis. A study comparing the effects of rofecoxib (voluntarily withdrawn from the market in 2004) and celecoxib to nonselective NSAIDs demonstrated similar renovascular effects.[40] In a large cohort of more than 1.4 million new NSAID users receiving care in the US Department of Veterans Affairs health care system, a greater risk of AKI (based on AKIN criteria) was found in nonselective versus COX-2 selective agents.[41] High-dose aspirin (defined as doses of at least 400 mg) was associated with the highest AKI risk. Naproxen, piroxicam, ketorolac, etodolac, indomethacin, sulindac, ibuprofen, and salsalate were also associated with a higher risk of AKI, whereas celecoxib, meloxicam, diclofenac, and other NSAIDs were not associated significantly with AKI. The highest risk was found in those using more than one NSAID, and in those switching from one agent to another. The lowest risk was found in those using the same agent continuously.[41,42] AKI risk was highest in the first 45 days of treatment initiation.[40] Sulindac may offer a "renal-sparing" effect. Sulindac is a prodrug that is converted to its active sulfide metabolite by the liver and then becomes reversibly oxidized back to its parent compound in the kidney; renal prostaglandin synthesis is essentially unaltered by sulindac. Cases of sulindac-induced renal dysfunction have been reported when the drug was administered to patients with cirrhosis and ascites.

CASE 29-1, QUESTION 2: A.W.'s cardiologist obtains a stat digoxin level, serum and urine electrolyte panels, and urinalysis. The digoxin level is reported as "not detectable" (target, 0.5–0.8 ng/mL). Other significant serum laboratory values include:

Na^+, 140 mEq/L
BUN, 56 mg/dL
SCr, 1.8 mg/dL

The urinalysis is significant for a urinary osmolality of 622 mOsm/kg, and specific gravity of 1.092. The urine electrolytes are significant for Na^+ of 12 mEq/L and creatinine of 102 mg/dL. What laboratory findings suggest functional AKI? Define the criteria used for the detection of AKI and staging of AKI in this patient.

A.W. has classic laboratory findings associated with poor renal perfusion (Table 29-3). It is important to compare the current and previous laboratory data to assess acute changes in renal function. Compared with last week, A.W.'s renal function has deteriorated based on substantial increases in BUN and SCr concentrations; BUN has increased nearly twofold and creatinine by 50% (SCr increased × 1.5-fold within 7 days). According to the AKIN/KDIGO criteria, the patient has stage 1 AKI. Renal demise is most likely due to functional AKI because the BUN:SCr ratio is greater than 20:1, suggesting poor renal blood flow, which is corroborated by other urinary indices such as the urinary Na^+ 12 mEq/L; specific gravity, 1.090 (elevated); urine osmolality, 622 mOsm/kg; and the calculated FENa, 0.1%. These values reflect the ability of the renal tubules to respond to vasopressin and aldosterone in an attempt to expand effective circulating volume and restore renal perfusion.

Another consideration is furosemide-induced volume depletion; however, the nondetectable serum digoxin level indicates likely noncompliance with his medications. A more likely explanation is poor renal perfusion because of his heart failure (i.e., low cardiac output).

CASE 29-1, QUESTION 3: How should A.W.'s prerenal azotemia be treated?

The presence of volume overload in the face of prerenal azotemia suggests a decreased effective circulating volume, most likely from poorly controlled HF. Restoring and improving A.W.'s cardiac output and renal perfusion will rapidly correct the prerenal azotemia. This can be achieved by (a) optimizing doses and assuring adherence to his heart failure medications (furosemide, lisinopril, metoprolol succinate, and digoxin); (b) controlling BP to a goal of lower than 140/90 mm Hg by decreasing both preload and afterload; and (c) modifying any drug therapy that has deleterious effects on the renal hemodynamics (e.g., NSAID). The specific therapies for controlling hypertension and improving cardiac output are presented in Chapter 9, Essential Hypertension, and Chapter 14, Heart Failure. Naproxen should be discontinued and substituted with acetaminophen to treat his osteoarthritis. Normal renal function should return in a few days after correction of the underlying causes.

Angiotensin-Converting Enzyme Inhibitor and Angiotensin Receptor Blocker–Induced Acute Kidney

Injury

CASE 29-2

QUESTION 1: G.B. is a 53-year-old white woman (height = 5 feet, 3 inches; weight = 170 pounds) with hypertension, coronary artery disease, peripheral vascular disease, and diabetes, for which she had been taking hydrochlorothiazide 25 mg PO daily, atorvastatin 10 mg PO daily, aspirin 81 mg PO daily, and insulin glargine 30 units subcutaneously once daily every morning. At last week's clinic visit, she had two consecutive BP readings of 187/96 and 193/95 mm Hg, respectively, measured 20 minutes apart. At that time, G.B.'s primary-care physician started her on lisinopril 5 mg PO daily. Other notable laboratory values at the time included HgA_{1c} 7.5% and urine albumin to creatinine ratio (ACR) 50 mg/g. The region was in the midst of a protracted heat wave with temperatures above 95°F and she claims not drinking much liquids. She returns to the clinic today for her 1-week follow-up appointment complaining of dizziness, dry mouth, and very little urine production during the past week. Laboratory values and vital signs obtained at this visit include the following:

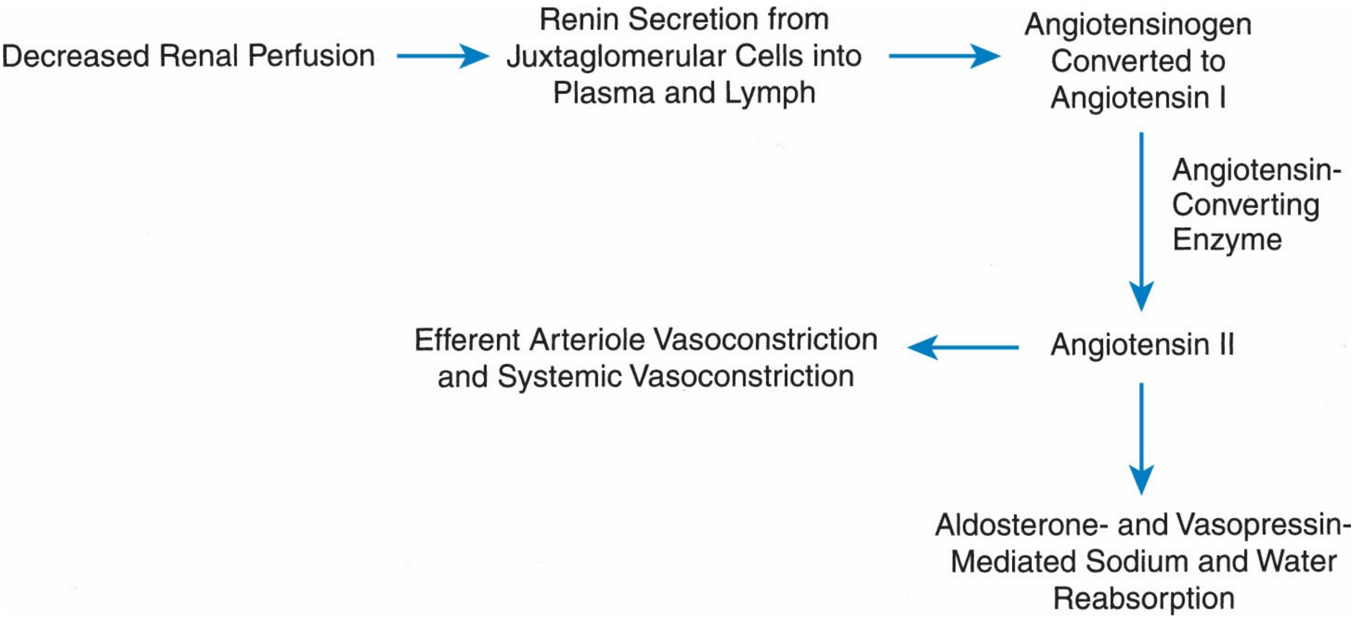
BP, 98/43 mm Hg
Hg, 15 g/dL
Hct, 45%
Na, 145 mEq/L
K, 5.2 mEq/L
BUN, 62 mg/dL
SCr, 2.7 mg/dL (baseline SCr, 1.0 mg/dL)
Why is G.B. experiencing AKI?

According to AKIN/KDIGO criteria, G.B. is diagnosed with stage 2 AKI most likely because of prerenal azotemia. Inhibition of the RAAS in patients with compromised renal blood flow is a common cause of functional AKI. A basic understanding of the effects of the RAAS on renal hemodynamics is necessary in this situation (Fig. 29-3). When renal perfusion is impaired, the juxtaglomerular cells of the kidney secrete renin into the plasma and lymph. Renin cleaves circulating angiotensinogen to form angiotensin I (AT I), which is further cleaved by angiotensin-converting enzyme (ACE) to form angiotensin II (AT II). AT II induces two physiologic events to improve renal perfusion. First, it directly causes systemic vasoconstriction, which shunts blood to the major organs, and indirectly increases intravascular volume through aldosterone- and vasopressin-mediated activity. Second, it preferentially vasoconstricts the efferent renal arteriole to maintain adequate intraglomerular hydrostatic pressure. Under conditions of decreased arterial pressure or effective circulating volume, the RAAS is activated and plasma renin and AT II activity are increased.[43,44]

CASE 29-2, QUESTION 2: Are there other factors that predispose patients to ACE inhibitor–induced AKI?

G.B. has extensive atherosclerotic disease indicated by the presence of coronary artery and peripheral vascular disease. Atherosclerosis not only affects major blood vessels but also the macrovasculature and microvasculature of the kidney; indeed, atherosclerosis is a major cause of renal artery occlusion and decreased renal perfusion. This activates the RAAS, which causes sodium and water reabsorption and AT II-mediated efferent arteriole vasoconstriction, in an attempt to restore normal renal perfusion and intraglomerular hydrostatic pressure.

The administration of ACE inhibitors directly inhibits the formation of AT II, which is necessary for efferent arteriole vasoconstriction. Consequently, the compensatory physiologic event that maintains G.B.'s renal blood flow is inhibited, thereby reducing her intraglomerular hydrostatic pressure and GFR. ACE inhibitors are contraindicated in patients with bilateral renal artery stenosis or unilateral stenosis in patients with a single functioning kidney.[45] In addition to the previous situation, three other general scenarios will result in the development of AKI with ACE inhibitors. First, conditions of sodium and water depletion (e.g., dehydration, overdiuresis, poor fluid intake, low-sodium diet) can increase the dependency of the efferent arteriole on AT II. Dehydration from diuretic use and decreased fluid intake during the heat spell may have compromised effective circulating volume and led to decreased renal blood flow in G.B. When ACE inhibitors are given in these situations, GFR can fall dramatically, and SCr rises. AKI can be averted by withholding the ACE inhibitor (or diuretic, or both) for a day and repleting the intravascular fluid volume with a saline-containing fluid (e.g., normal saline or 0.45% saline). The ACE inhibitor can be restarted at the same dose after adequate hydration when SCr returns to baseline. Second, ACE inhibitors can decrease the mean arterial pressure to such a degree that renal perfusion cannot be sustained. This is more likely to occur with long-acting agents or in situations in which the pharmacologic half-life of the ACE inhibitor is prolonged (e.g., preexisting renal disease). Finally, ACE inhibitors may precipitate AKI in patients who are taking concomitant drugs with renal afferent arteriole vasoconstricting effects, most notably cyclosporine and NSAIDs. In AKI, another important consideration is thiazides (except metolazone), which are less effective in the presence of ClCr <30 mL/minute and can be restarted when renal function improves.



Decreased Renal Perfusion
Renin Secretion from Juxtaglomerular Cells into Plasma and Lymph
Angiotensinogen Converted to Angiotensin I
Angiotensin-Converting Enzyme
Angiotensin II
Efferent Arteriole Vasoconstriction and Systemic Vasoconstriction
Aldosterone- and Vasopressin-Mediated Sodium and Water Reabsorption

Figure 29-3 Compensatory hormonal mechanisms of decreased renal perfusion.

CASE 29-2, QUESTION 3: How should G.B.'s ACE inhibitor–induced AKI be managed?

Patients who are receiving ACE inhibitors should be monitored judiciously with regard to their SCr and electrolyte concentrations. Once an ACE inhibitor is initiated, an increase in SCr of 20% to 30% can be expected.[44] This slight increase should not worry clinicians, because SCr typically normalizes within 2 to 3 months. SCr increases greater than this along with reduced urine output signal AKI, however. AKI related to ACE inhibitors is usually reversible, principally because the AKI is caused by inadequate glomerular capillary pressure, which is restored as soon as sufficient AT II is produced. This normally takes 2 to 3 days to re-equilibrate. Anecdotally, AKI appears to develop more commonly in hypotensive patients or in those with intravascular volume depletion (e.g., patients with HF receiving high-dose diuretics, inadequate fluid intake with diuretic use). In these conditions, it is prudent to replete the intravascular fluid volume or temporarily discontinue diuretic therapy until renal function improves. G.B.'s ACE inhibitor therapy should be temporarily discontinued and reinstituted when she has a normalized intravascular volume and is hemodynamically stable and kidney function has returned to baseline or stabile kidney function is established. See Chapter 14, Heart Failure, for a discussion on the use of ACE inhibitors and concurrent diuretic therapy in patients with heart failure.

CASE 29-2, QUESTION 4: Do angiotensin II–receptor blockers (ARBs) cause less AKI compared with ACE inhibitors?

The ARBs competitively inhibit the angiotensin II receptor. At least two subtypes of the angiotensin II receptors exist: AT1 and AT2. The ARBs exert their pharmacologic effect at the AT1 receptor subtype, which is responsible for most, if not all, of the cardiovascular effects of angiotensin II, such as vasoconstriction, aldosterone release, and β-adrenergic stimulation. Few differences are seen in the incidence of AKI between ACE inhibitors and ARBs[45] and one should not be interchanged with the other in an attempt to decrease AKI risk. See Chapter 14, Heart Failure, for further discussion.

HgA_{1c} and urine ACR are elevated. The patient may be at risk for diabetic nephropathy from uncontrolled diabetes. Initially, albuminuria (at least 2 out of 3 elevated ACR values >30 and <300 mg/g within 3 months) is considered a renal marker indicative of early stage CKD with or without an increase in baseline SCr. ACE inhibitors or ARBs are prescribed as anti-proteinuric agents to manage albuminuria and delay the progression of CKD with or without underlying hypertension. ACE inhibitors are the preferred anti-proteinuric agents in type 1 diabetes, whereas ARBs are preferred in type 2 diabetes and in patients intolerant to cough associated with ACE inhibitors. After AKI resolves in G.B., an ACE inhibitor is appropriate to consider treating hypertension and delay the progression of CKD.

INTRINSIC ACUTE KIDNEY INJURY

Intrinsic AKI is a general term that connotes damage at the parenchymal level of the kidney. The term acute tubular necrosis is often used to describe this type of AKI, but this is a histologic diagnosis that describes only one of several intrinsic disorders. Pragmatically, intrinsic AKI can be subdivided into vascular, glomerular, or tubular disorders.

Disorders involving the large renal vessels are relatively uncommon. Acute renal artery or vein occlusion can be caused by vasculitis, atheroembolism, thromboembolism, dissection, or clamping of the ascending aorta during surgery. To affect BUN and Scr, occlusion must be bilateral, or it can be unilateral in patients with concomitant renal insufficiency or one functioning kidney. Reduced blood flow to the renal microvasculature and glomeruli also can result in AKI. Common examples are rapidly progressing glomerulonephritis (RPGN) and vasculitis. If these conditions become sufficiently severe, they can cause ischemia, resulting in superimposed ATN. Any disorder that produces tubular ischemia, such as prolonged hypotension or shock syndromes, can result in ATN.

Nephrotoxic drugs are a common cause of ATN, especially when given in septic or volume-contracted patients. The various mechanisms by which drugs can cause ATN are explained in detail later in this chapter. Although relatively uncommon, drug-induced AIN is another type of intrinsic AKI. This is a hypersensitivity reaction that results from the formation of drug–antibody complexes that subsequently deposit in the glomerular membrane.

Acute Glomerulopathies

POSTSTREPTOCOCCAL GLOMERULONEPHRITIS

CASE 29-3

QUESTION 1: B.M. is an 18-year-old white male college freshman (height = 5 feet, 8 inches; weight = 150 pounds) in otherwise good health who recently developed strep throat. He received a 10-day course of amoxicillin, which cleared the infection. He returns to the student health center after completing his 10-day course complaining of "puffy eyes," swelling in his legs, a cough productive of clear sputum, and decreased urine output that appears "tea-colored." Other than the amoxicillin, he is not on any medication. Baseline records from a routine physical examination 2 months ago reveal a BUN and SCr of 10 and 0.8 mg/dL, respectively, and a BP of 120/80 mm Hg. Today, the physical examination is significant for a BP of 176/95 mm Hg, 2+ peripheral edema, and bilateral pulmonary rales. The urinalysis is significant for gross hematuria, nephritic-range proteinuria, RBC and WBC casts, and epithelial cells. B.M.'s SCr has increased to 7.1 mg/dL. Based on the history, physical examination, and laboratory findings, what is the most likely cause of AKI in this patient?

B.M.'s recent history of a streptococcal infection with the development of AKI suggests poststreptococcal glomerulonephritis (PSGN), which results from the formation of antibodies against streptococcal antigens. The streptococcal–antigen immune complexes are deposited in the glomerulus, resulting in complement, cytokine, and clotting cascade activation; neutrophils and monocytes attack the glomerulus causing glomerulonephritis. The onset of PSGN is usually 7 to 21 days after the start of the pharyngeal infection. PSGN is the most common acute-onset, immune-mediated, diffuse glomerulopathy. It primarily affects children, although it can affect any age group and is more prevalent in males than in females. Certain serologic subtypes of group A β-hemolytic streptococci, known as nephritogenic strains, cause PSGN. The M and T proteins located in the bacterial cell wall are used to classify streptococci. Nephritogenicity has been shown with certain M serotypes (e.g., 1, 2, 4, 12, 18, 25, 49, 55, 57, and 60).[46] Strains that follow pharyngeal infections (e.g., strep throat) include types 1, 3, 4, 6, 12, 25, and 49. Type 49 is the most prevalent strain worldwide. The overall risk of developing PSGN by the M type 49 subtype when present in the throat is about 5% and increases to 25% if it is found in the skin. Acute PSGN has also been described after infection with group C streptococci in epidemics outside of the United States.[47] Positive diagnosis of PSGN requires identification of a nephritogenic strain; objective urinalysis findings suggestive of glomerular damage, such as proteinuria, hematuria, and casts; and elevated streptococcal antibody titers.

B.M. exhibits the classic physical and laboratory findings associated with PSGN. The pertinent positive physical findings include periorbital, pulmonary, and peripheral edema; tea-colored urine; hypertension; and decreased urine output. Edema is a common manifestation, with periorbital edema typically being the first to appear. Reduced GFR, proteinuria, and sodium retention by the kidney all contribute to edema formation. When protein, principally albumin, is lost in the urine, the intravascular oncotic pressure declines, causing a shift of fluid into the extravascular space. The loss of intravascular volume stimulates sodium and water reabsorption by the kidney via aldosterone and vasopressin, which often produces stage 1 to 2 hypertension.

Pertinent laboratory data in B.M. include elevated SCr, and urinalysis positive for hematuria, proteinuria, WBC casts, and epithelial cells. Hematuria, which is found in almost all patients with PSGN, accounts for the reddish-brown, tea-colored urine. Other commonly found urine sediments include cellular casts and hyaline and granular casts. Oliguria is common in PSGN, but anuria is rare.

Given that B.M. has received a 10-day course of amoxicillin, it is unlikely that throat cultures for the nephritogenic group A hemolytic streptococcal strain will be positive. Cultures of close contacts may, however, be positive for the streptococcal strain, even if they are asymptomatic. The presence of circulating antibodies to the nephritogenic streptococcal strains indicates recent exposure. The antistreptolysin O (ASO), antihyaluronidase (AHase), antideoxyribonuclease B (ADNase B), and antinicotyladenine dinucleotidase (NADase) antibody titers can be measured clinically. ASO titers begin to rise 2 weeks after pharyngeal infection, peak at 4 weeks, and slowly decline over the course of 1 to 6 months. No correlation exists between degree of ASO rise and nephrogenicity. In fact, ASO titers may not be elevated at all if early antibiotic treatment is initiated or in cases of streptococcal skin infections. The use of ADNase and AHase titers is more specific to detect recent infection in these situations.

CASE 29-3, QUESTION 2: Are there other tests that can be used to confirm this diagnosis?

The streptozyme test, which can be used clinically for rapid screening purposes, uses several antistreptococcal antibody assays. False-positive and false-negative results are common, however, because of cross-reactivity between the antibody and normal collagen.

Serial complement determinations may be of value in diagnosing PSGN. Decreased levels of C3 protein and hemolytic complement activity (CH50) are observed in nearly all patients with active PSGN. Serum C3 levels can fall by nearly 50% of normal in the first weeks of infection and return to normal within 8 weeks after infection. No correlation, however, exists between the degree of C3 depression and severity of nephritis. Circulating antibody complexes of C3 can be found in patients with acute infection.

Renal biopsy is rarely needed, but it may be prudent in patients who present with atypical symptoms, such as anuria, prolonged oliguria, marked azotemia, hematuria for more than 3 weeks, or in those who have no streptococcal antibody titers.

CASE 29-3, QUESTION 3: What are the therapeutic goals and treatment options for PSGN?

The therapeutic goals are to minimize further kidney damage and to provide symptomatic relief for B.M. The underlying streptococcal infection should be treated with appropriate antibiotics, but as illustrated by B.M., this has no effect in preventing PSGN. Family members and close contacts of the infected patient should receive antibiotic prophylaxis as well. Restriction of protein to 0.8 g/kg/day may be beneficial in patients with marked proteinuria, and antihypertensive drugs can be used on a short-term basis to control BP. Sodium and water restriction is beneficial in reducing edema, and loop diuretics may be used as needed for symptomatic pulmonary or peripheral edema. Close monitoring of electrolytes is warranted if diuretics are used. Dialysis is rarely required. Given his age and previous health, B.M.'s prognosis is very good. In general, prognosis is excellent in youth, but significantly worse in the elderly and in patients with other risk factors for CKD, such as diabetes and hypertension.[47]

RAPIDLY PROGRESSIVE GLOMERULONEPHRITIS

CASE 29-3, QUESTION 4: Are there other glomerulopathies that cause AKI?

Yes. Rapidly progressive glomerulonephritis (RPGN), also called crescentic glomerulonephritis, is a clinical syndrome of rapid decline in renal function (from days to weeks) combined with the hallmark findings of gross hematuria, nephritic syndrome with proteinuria, and the presence of extensive glomerular crescents (>50% of glomeruli) on renal biopsy. It is not uncommon for patients with RPGN to have a 50% decline in GFR in only a few weeks. RPGN is a medical emergency, and treatment success depends on how early therapy is initiated. If left untreated, progression to end-stage renal disease or death is almost certain.

Idiopathic RPGN is divided into three categories based on immunofluorescence microscopy. Type I idiopathic RPGN is characterized by linear deposition of immunoglobulins, primarily IgG, along the glomerular basement membrane (GBM) indicating anti-GBM antibodies. Type II idiopathic RPGN is identified by granular immunoglobulin and complement depositions in the glomerular microvasculature and mesangium, suggesting immune complex deposition. Type III idiopathic RPGN is also called pauci-immune because there are no hallmark immunoglobulin or complement findings on immunofluorescence microscopy. Type III idiopathic RPGN is identified by the presence of circulating antineutrophil cytoplasmic antibodies (ANCA). Type IV, known as double-antibody disease, is characterized by anti-GBM antibodies and ANCA seen in Types I and III RPGN.[48]

Multisystem vasculitic disorders that result in glomerular capillary inflammation are the most common cause of RPGN.[49] Many of these patients present with nonspecific flulike symptoms such as fever, weight loss, myalgia, and malaise with proteinuria and hematuria.[50] Uremic symptoms can occur with severe disease. The presence of AKI with pulmonary congestion, cough, hemoptysis, or dyspnea suggests

Wegener's granulomatosis. The treatment for autoimmune RPGN generally involves various regimens of immunosuppressive agents. Corticosteroid monotherapy (oral or "pulse" intravenous) or combined with either cyclophosphamide or rituximab have been investigated. Rituximab may improve renal outcomes in Type III idiopathic RPGN; in addition to anti–B-cell therapy, therapy directed at T cells may improve renal outcome.[51] Plasmapheresis is also a non-pharmacological treatment option in selected patients. A more detailed discussion of glomerulonephritis is presented in Chapter 28, Chronic Kidney Disease.

NONSTEROIDAL ANTI-INFLAMMATORY DRUG–INDUCED GLOMERULOPATHY

CASE 29-3, QUESTION 5: Which drugs cause glomerulonephropathy?

Minimal-change disease and membranous nephropathy have been associated with NSAID use.[52] The mechanism is probably related to NSAID-induced inhibition of the cyclo-oxygenase pathway, which leads to increased arachidonate catabolism and increased proinflammatory leukotriene production. The hallmark feature of NSAID-induced nephropathy is nephrotic-range proteinuria. The nephropathy resolves slowly over the course of several months once the NSAID is discontinued.

TUBULOINTERSTITIAL DISEASES

Acute Tubular Necrosis

ATN arises most often from ischemia or drug-induced causes.[53] Prolonged prerenal conditions, such as hypotension, surgery, overwhelming sepsis, or major burns, can lead to ischemic ATN. Unlike prerenal azotemia, tubular cell death occurs in ATN, and immediate volume resuscitation will not reverse the damage. The pathophysiology of ATN is complex and remains unclear. It is currently thought that when tubular cells die, they slough off into the tubule lumen and contribute to cast formation. The casts completely obstruct the tubule lumen and increase intratubular pressure, which causes a back leak of ultrafiltrate across the tubular basement membrane (Fig. 29-4). The aforementioned processes are mediated by a variety of substances, including calcium, phospholipases, and perhaps growth factors as well as free radical and protease activation.

TREATMENT WITH DIURETICS AND DOPAMINE

CASE 29-4

QUESTION 1: V.B. is a 86-year-old white man (height = 5 feet, 2 inches; weight = 138 pounds), who was admitted for elective aortic valve replacement secondary to severe aortic stenosis. He became hypotensive during surgery, requiring aggressive fluid resuscitation. He is now in the ICU and requires vasopressors for hemodynamic support. His BUN is 88 mg/dL and his SCr is 3.5 mg/dL today. His renal function tests have remained at these levels for the past 3 days. His baseline SCr before surgery was 1.2 mg/dL. Despite IV fluids, V.B. is oliguric with a urine output of 15 mL/hour (350 mL/day). Do diuretics and dopamine have a role in treating ATN?

It is well documented that patients with nonoliguric renal failure have significantly better outcomes compared with those with oliguria. This is probably because patients who are nonoliguric have less extensive renal damage and are better able to maintain fluid and electrolyte balance. Loop diuretics have been used in established ATN in an attempt to convert patients with oliguria to a nonoliguric state despite the lack of conclusive evidence for their benefits. Numerous clinical trials, however, have failed to demonstrate improved mortality or duration of azotemia in oliguric patients who receive loop diuretics, despite improved urine output.[9] Two large systematic reviews of the primary literature convincingly showed that diuretic therapy plays little role in altering the course of AKI, decreasing length of hospitalization, or helping recover renal function.[54,55] These data suggest that although patients who are nonoliguric generally have better outcomes, converting a patient from oliguria to nonoliguria through pharmacologic intervention does not improve patient outcomes. Currently, the only role that diuretic administration has in patients with established ATN is to increase urine output, which facilitates fluid, electrolyte, and nutritional support.[9]

Another controversy that has been debated extensively in the literature is the use of dopamine in patients with established ATN. Dopamine is a catecholamine that stimulates dopaminergic receptors at low dosages (1–3 mcg/kg/minute), and α- and β-receptors at higher dosages (5–20 mcg/kg/minute). Animal and human studies have demonstrated that low-dose dopamine improves renal blood flow by inducing afferent arteriolar vasodilation. No data, however, support the use of dopamine in the treatment of established AKI. A meta-analysis of 61 clinical trials including nearly 3,500 patients failed to detect any significant improvement in variables such as occurrence of AKI, need for renal replacement therapy, or mortality.[56] Unequivocally, dopamine has no role in preventing or treating AKI.

Other modalities such as fenoldopam or atrial natriuretic peptide (ANP) have not been shown to be conclusively beneficial to treat AKI and hence are not recommended to be used.[9] RRT would be the most appropriate to use if life-threatening changes in fluid, electrolytes, or acid–base balance are noted.

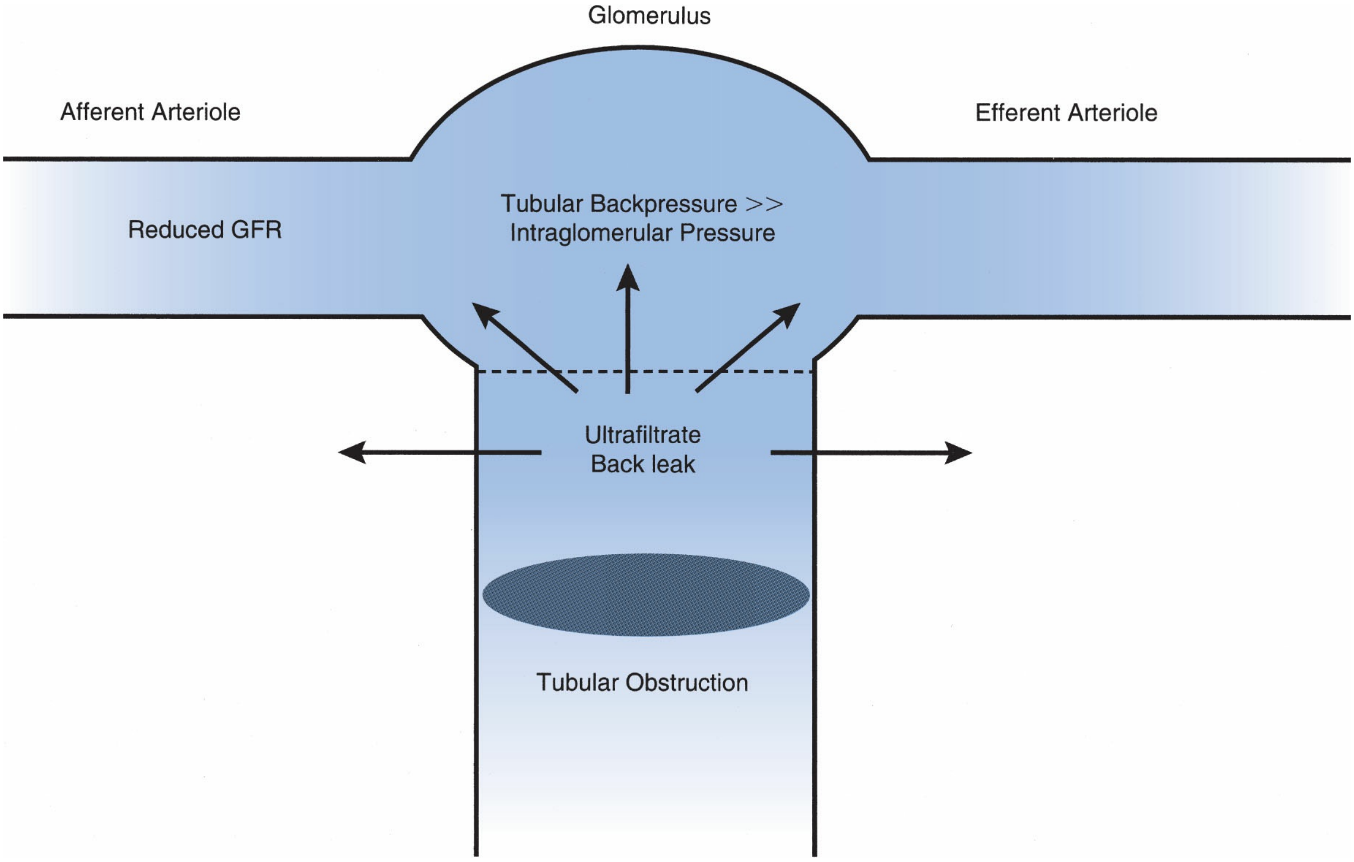


Figure 29-4 Schematic of acute tubular necrosis (ATN). The process is initiated by ischemia or nephrotoxin exposure that leads to tubular cell death. The cellular debris sloughs off and obstructs the proximal tubule lumen. Once the nephron is obstructed, a back leak of the glomerular ultrafiltrate occurs across the tubular basement membrane and impairment of glomerular filtration is seen. During the recovery phase of ATN, the obstructive cellular casts are released into the urine and filtration begins to normalize. GFR, glomerular filtration rate.

Radiocontrast Media–Induced Acute Tubular Necrosis

CASE 29-5

QUESTION 1: K.S., a 74-year-old black man (height = 5 feet, 9 inches; weight = 210 pounds), presents to the emergency department complaining of chest pain. His medical history is significant for advanced type 2 diabetes mellitus, with retinopathy, peripheral vascular disease, and advanced coronary artery disease. Based on cardiac enzymes, K.S. is ruled in for STEMI. He is taken to the cardiac catheterization laboratory for a percutaneous coronary intervention. Immediately before the procedure, K.S. is given iopamidol (Isovue, Bracco Diagnostics Inc., Princeton, NJ, USA) a nonionic, low-osmolar radiocontrast to enhance visualization of his cardiac arteries. His admission BUN is 37 mg/dL and SCr is 1.5 mg/dL. Two days later, pertinent laboratory findings include a BUN and SCr of 60 and 2.0 mg/dL, respectively, and his urine output is 700 mL/day. Why did AKI develop in K.S.? How is his diagnosis substantiated by his clinical findings?

Radiocontrast media administration is one of the most common causes of drug-induced ATN. Although no set criteria exist for its diagnosis, it is generally considered after radiocontrast exposure when an increase in SCr of 0.5 mg/dL or 25% greater than baseline occurs in 24 to 48 hours, peaks at 3 to 5 days, and returns to baseline in 1 to 3 weeks.[57,58] The American College of Radiology has recommended using the AKIN criteria requiring smaller changes in serum creatinine occurring within 48 hours after the administration of iodinated contrast media to define contrast-induced nephropathy (CIN) in order to standardize the varying definitions found in the literature.[59] CIN usually presents as a nonoliguric ATN, as observed in K.S., whose urine output is more than 400 mL/day. It is also differentiated from other forms of ATN in that the FE_{Na} is usually less than 1% (vs. the typical >2%). The degree of creatinine rise and the presence of oliguria are widely variable. Because of the lack of an accepted CIN definition and differences in both clinical trial design and populations studied, estimating the true prevalence of CIN is daunting. Nevertheless, patients without risk factors have a relatively minute risk of developing CIN; for those with recognized risk factors, prevalence may approach 50%.[60]

The mechanisms by which radiocontrast media induce AKI are complex. Initially, the radiocontrast medium produces renal vasodilation and an osmotic diuresis. This, however, is followed by intense vasoconstriction in the medullary portion of the kidney, which has been demonstrated by significant decreases in medullary Po_2 after contrast administration.[61] The ischemia is compounded by the increased medullary oxygen consumption because of the osmotic diuresis. Consequently, disequilibrium exists between oxygen supply and demand, creating ischemic ATN. Various vasoactive substances are suspected of decreasing medullary blood flow, including oxygen free radicals, prostaglandins, endothelin, nitric oxide, angiotensin II, and adenosine. Endothelin and adenosine are potent vasoconstrictors that are directly released from endothelial cells on exposure to radiocontrast media.

CASE 29-5, QUESTION 2: What risk factors did K.S. have for developing CIN?

The documented risk factors for CIN are listed in Table 29-5. Any condition that decreases renal blood flow increases the risk of nephropathy. At-risk patient populations include individuals with underlying diabetic nephropathy or eGFR <60 mL/minute/1.72 m^2, heart failure, or volume depletion, or those receiving aggressive diuretic regimens. Contrast volume administered during the imaging procedure as well as type of contrast remain additional risk factors.[62] The use of the ionic high-osmolar or ionic low-osmolar contrast products increases the risk of nephropathy, as well as the previously discussed medications that markedly reduce renal perfusion (e.g., diuretics, NSAIDs, COX-2 inhibitors, ACE inhibitors, and ARBs). However, newer nonionic low-osmolar agents may be less nephrotoxic than older agents, but still can cause nephrotoxicity in patients at risk. Nonionic iso-osmolar contrast appears to be better tolerated.[63]

Table 29-5

Proven Risk Factors for Developing Radiocontrast Media–Induced Acute Tubular Necrosis

Diabetic nephropathy
Chronic kidney disease
Severe heart failure
Diabetes and multiple myeloma
Volume depletion and hypotension
Dosage and frequency of contrast administration
Ionic radiocontrast agents

On the basis of the published literature, gadolinium-based contrast (GBC) agents are less nephrotoxic than iodinated radiocontrast; however, when GBC agents are used in high dosage with arterial injection in patients with advanced kidney disease, AKI can occur. More concerning is the development of debilitating nephrogenic systemic fibrosis (NSF), which is sometimes fatal. There is no cure for NSF. Patients with AKI or CKD with GFR <30 mL/minute, who have had imaging studies (e.g., magnetic resonance angiography) with GBC agents are at high risk for developing NSF. The U.S. Food and Drug Administration (FDA) has issued an advisory Black Box Warning to avoid using these currently approved GBC agents (Ablavar, Doterem, Eovist, Magnevist, Multihance, Omniscan, Optimark, Prohance) in AKI and stage 4 and 5 CKD.[64–66]

K.S. is at high risk for developing radiocontrast-induced ATN. He is volume depleted, as evidenced by his admission BUN:SCr ratio, which is greater than 20:1. Second, it is very likely that K.S. has underlying diabetic nephropathy, as evidenced by his elevated admission SCr. The presence of retinopathy, coronary artery disease, and peripheral vascular disease suggest long-term uncontrolled diabetes mellitus, a risk factor for nephropathy.

PREVENTION

CASE 29-5, QUESTION 3: What strategies could have been performed in K.S. to prevent the occurrence of CIN?

Attempts have been made to minimize or prevent CIN using a variety of approaches. Decreasing contact time and the concentration of contrast media within the kidney tubule lumen may reduce its direct toxic effects. A higher urine output is associated with a lower incidence of CIN in high-risk patients.[67,68] Volume expansion is a rational approach to prevent renal dysfunction in this population because human and animal data have revealed dehydration as a major risk factor for developing CIN. Intravenous hydration with normal saline, hypotonic saline (0.45% sodium chloride), and sodium bicarbonate in dextrose 5% and water have all shown benefits in preventing CIN in high-risk patients. Infusion rates usually start at 1 mL/kg/hour to maintain a goal urine output of 150 mL/hour.

Sodium bicarbonate may be of value, but larger multicenter studies are needed to determine its true effectiveness.[68] Notably, sodium bicarbonate may be more beneficial in decreasing the incidence of radiocontrast nephropathy relative to other fluids because it reduces oxygen free radicals in the renal medulla and, therefore, increases the medullary pH. However, sodium overload is problematic and sodium bicarbonate should be avoided in compromised cardiac states.

Data suggest normal saline should be infused at least 6 hours before and 12 hours after the imaging study to adequately reduce the risk of developing nephropathy. In contrast, sodium bicarbonate should be infused 1 hour before and 6 hours after the imaging study. The antioxidant N-acetylcysteine (NAC) has also been used for its renal-sparing effects relative to radiocontrast media, but its role in preventing CIN remains unclear.[69] NAC is believed to work by protecting renal tubule cells from apoptosis related to the reactive oxygen species.[70] Although much data have been generated with NAC, many of these studies have significant pitfalls, including relatively small sample size; single-center design; heterogeneity of patient populations; differing doses, dosage forms, and schedules of NAC therapy; and differing hydration regimens. Therefore, trying to delineate meaningful conclusions from this body of literature is daunting. Given the safety profile and minimal cost impact as well as the significant morbidity associated with CIN in high-risk patients, its continued use is not inappropriate. At this time, recommending a specific dose of NAC is difficult. The commonly accepted regimens at many institutions is 600 or 1,200 mg orally twice daily the day before and the same day of the contrast procedure for a total of four doses along with concomitant intravenous hydration therapy.[71] Higher doses (total of 6,000 mg over 48 hours) may be required for high-risk patients (those with CKD or HF) and needs further investigation.[72]

Currently, a large randomized, double-blind, multicenter trial ongoing trial, The Prevention of Serious Adverse Events following Angiography (PRESERVE), [73] will compare the effectiveness of intravenous bicarbonate versus intravenous normal saline and oral NAC versus oral placebo for prevention of contrast-induced AKI. The trial (ClinicalTrials.gov NCT01467466) will enroll 8,680 high-risk patients undergoing coronary or noncoronary angiography.

Another important point is that the administration of diuretics such as mannitol and furosemide should be avoided.[74] These diuretics result in volume depletion and increase oxygen demand in the medullary portion of the kidney when diuresis occurs, thereby counteracting the benefits of hydration.

Other therapeutic modalities for the prevention of CIN have been studied. A systematic review and meta-analysis of aminophylline and theophylline have affirmed a renoprotective effect in patients who have underlying CKD; however, large-scale clinical trials are lacking.[75]Although the use of calcium-channel blockers theoretically seems rational to prevent contrast-induced ATN, limited clinical data exist. HMG CoA reductase inhibitors have been proposed for prevention of CIN given their antioxidant and anti-inflammatory properties; however, recent studies have not shown a benefit.[76,77] Limited data suggest that ascorbic acid before and after the procedure may be beneficial in preventing contrast nephropathy given its antioxidant effects[78]; however, a recent published report comparing ascorbic acid to NAC showed a greater benefit of high-dose NAC than ascorbic acid in preventing CIN in patients at risk.[79] High doses and long-term use of ascorbic acid should be avoided because of the risk of hyperoxalurea, oxalate-containing urinary stones, and renal damage.

When possible, alternative imaging studies that do not require radiocontrast should be attempted. If this is not practical, the lowest effective dose of nonionic low-osmolar or iso-osmolar radiocontrast media should be used. Concomitant drug therapy that can impair renal perfusion, such as diuretics, NSAIDs, COX-2 inhibitors, ACE inhibitors, and ARBs, should be discontinued 1 day before and 1 day after radiocontrast administration. Metformin

---

is also a risk factor. It is not a nephrotoxin; however, its use has been associated with the development of AKI, systemic complications, and death in rare cases. Metformin should also be discontinued 1 day before giving radiocontrast media and held for at least 2 days after the imaging study because it may cause lactic acidosis if patients experience AKI. If patients are receiving calcium-channel blockers for underlying cardiovascular disease, no change in therapy is warranted. All patients should be well hydrated with normal saline or sodium bicarbonate fluids before and after radiocontrast administration to prevent CIN. The addition of NAC is optional.

CASE 29-5, QUESTION 4: What treatment options are available for established radiocontrast-induced ATN?

Few data exist regarding treatment of existing radiocontrast-induced ATN. The acute management largely involves supportive care that includes strict fluid and electrolyte management to prevent undue sequelae. Approximately 25% of patients will require temporary dialysis therapy; patients who are oliguric generally require long-term dialysis therapy. As already noted, attempts to convert oliguria to nonoliguria with furosemide and mannitol have been largely unsuccessful.

Aminoglycoside-Induced Acute Tubular Necrosis

CASE 29-6

QUESTION 1: T.G. is a 81-year-old, 80 kg white male (height 5 feet, 10 inches) being treated for Streptococcus bovis prosthetic valve endocarditis. T.G. is known to have systolic congestive heart failure with an ejection fraction of 25%. T.G. has a low BP at 90/50 mm Hg, pulse 110 beats/minute. Since admission, T.G. has received ceftriaxone 2 g IV daily, and gentamicin 80 mg IV q8 hours. Today, (hospital day 7), significant laboratory values are as follows:

BUN, 67 mg/dL
SCr, 5.4 mg/dL (baseline 0.9 mg/dL)
WBC count, 16,700 cells/µL with continued left shift
FE_{Na} 3%

During the last 2 days, T.G.'s urine output has steadily declined, and today it is 700 mL/24 hours. A urinalysis revealed many WBCs, 3% RBC casts, brush-border cells, and granular casts with an osmolality of 250 mOsm/kg. A serum trough gentamicin concentration obtained with the last dose is 6 mg/L (target, <1.0 mg/L). Given the history and laboratory data, what is the likely source of T.G.'s AKI?

The source of AKI in this situation is likely multifactorial (Table 29-2). Low renal perfusion secondary to low ejection fraction can result in prolonged renal ischemia. Second, T.G. has received 1 week of gentamicin, a well-known nephrotoxic antibiotic. The risk factors for developing aminoglycoside nephrotoxicity are listed in Table 29-6. The latest gentamicin trough concentration of 6 mg/L is far higher than the target value of less than 1 mg/L for a traditional 3-times-daily dosing regimen used for synergy for bacterial endocarditis.[80] Given the laboratory data (Table 29-3) and the clinical course of prolonged hypotension, vasopressor, and aminoglycoside administration, nonoliguric ATN is the most likely diagnosis.

PRESENTATION

CASE 29-6, QUESTION 2: How does aminoglycoside-induced ATN present, and what are the mechanisms of toxicity?

Table 29-6

Risk Factors for Developing Aminoglycoside Nephrotoxicity

Patient Factors
Elderly
Underlying renal disease
Dehydration
Hypotension and shock syndromes
Hepatorenal syndrome
Aminoglycoside Factors
Aminoglycoside choice: gentamicin > tobramycin > amikacin
Therapy >3 days
Multiple daily dosing
Serum trough >2 mg/L
Recent aminoglycoside therapy
Concomitant Drug Therapy
Amphotericin B
Cisplatin
Cyclosporine

Foscarnet
Furosemide
Radiocontrast media
Vancomycin

T.G. illustrates the typical presentation of aminoglycoside-induced nephrotoxicity. Generally, the onset occurs after 5 to 7 days of treatment and presents as a hypo-osmolar, nonoliguric renal failure with a slow rise in SCr.[81] Because of the tubular necrosis that occurs, the urinalysis is often positive for low-molecular-weight proteins, tubular cellular casts, epithelial cells, WBCs, and brush-border cells.[82] T.G.'s plasma and urinary laboratory indices are consistent with those listed for ATN in Table 29-3.

The mechanism of aminoglycoside-induced ATN is complex. Approximately 5% of filtered aminoglycoside is actively reabsorbed by the proximal tubule cells. These agents are polycationic and bind to the negatively charged brush-border cells within the tubule lumen. Once attached, these agents undergo pinocytosis and enter the intracellular space, setting off complex biochemical events that result in the formation of myeloid bodies. With continued formation of myeloid bodies, the brush-border cells swell and burst, releasing large concentrations of aminoglycoside and lysosomal enzymes into the tubule lumen, thereby beginning a cascade of further tubular destruction.[81,83] The following rank order of nephrotoxicity has been collated from human and animal data: neomycin > gentamicin > tobramycin > amikacin > netilmicin > streptomycin.[82]

EXTENDED-INTERVAL DOSING

CASE 29-6, QUESTION 3: Is "extended-interval" aminoglycoside dosing less nephrotoxic than multiple daily dosing regimens?

Extended-interval aminoglycoside dosing entails the administration of one large daily aminoglycoside dose instead of multiple daily dosing. This dosing scheme takes advantage of the concentration-dependent killing activity and post-antibiotic effect observed with aminoglycosides while minimizing time-dependent toxicity.

The net effect of this dosing scheme, purportedly, is greater efficacy with reduced toxicity. Aminoglycoside nephrotoxicity is a function of drug exposure, and it might be minimized with extended-interval dosing because of saturable uptake kinetics in the proximal tubule. That is, only a maximal amount of aminoglycoside is transported into the tubule cell, no matter how much aminoglycoside is present in the tubule. Consequently, once saturation occurs, the remaining aminoglycoside concentration passes through the proximal tubule without being absorbed, and is excreted in the urine. Accumulation is therefore averted.[84] This concept is supported by studies demonstrating that continuous-rate gentamicin infusions, which produce sustained low plasma concentrations, result in greater proximal tubule uptake and nephrotoxicity than extended-interval regimens. This is probably because the achieved drug concentrations are well below those required to saturate the uptake mechanism. Extended-interval dosing results in very high peak concentrations to improve efficacy and generally undetectable trough concentrations before the next dose, thus minimizing accumulation. Numerous clinical trials and meta-analyses have compared the efficacy and toxicity of extended-interval aminoglycoside dosing with conventional multiple daily dosing regimens. For endocarditis, aminoglycosides, such as gentamicin 1 mg/kg q8 hours or 3 mg/kg once daily, adjusted for renal function are recommended by the American Heart Association for the management of selected cases of bacterial endocarditis for their synergistical activity with the β-lactams. The extended interval dosing is less well studied for endocarditis.[80] In summary, extended-interval aminoglycoside dosing appears to result in similar or greater efficacy, with similar or reduced toxicity. This dosing schedule is also less costly when considering therapeutic drug monitoring, preparation, and administration costs. Although the typical extended interval in patients with normal renal function is dosing every 24 hours, the interval may have to be prolonged to several days in patients with renal failure.

Drug-Induced Acute Interstitial Nephritis

Drug-induced AIN accounts for approximately 1% to 3% of all AKI cases.[85–89] A variety of antibiotics, such as penicillins, cephalosporins, quinolones, particularly ciprofloxacin, sulfonamides, and rifampin, as well as NSAIDs, loop diuretics, thiazide-like diuretics, and proton pump inhibitors, have been implicated as common drug causes of AIN. The pathophysiology of this reaction is not well understood; it is suspected that either humoral or cell-mediated immune mechanisms or both are involved.[90] Humoral immune reactions occur within minutes to hours of drug exposure and involve the drug or its metabolite acting as a hapten that binds to host proteins, making them antigenic. The drug–protein antigens become lodged in the renal tubules, which initiate the inflammatory cascade. Cell-mediated injury can occur days to weeks after drug exposure and is identified by the presence of mononuclear inflammation and the lack of detectable immune complexes. This suggests a delayed hypersensitivity rather than a direct cytotoxic effect from a given drug. Both immune mechanisms probably contribute to the development of drug-induced AIN.

PENICILLIN-INDUCED ACUTE INTERSTITIAL NEPHRITIS

CASE 29-7

QUESTION 1: J.S. is a 50-year-old Hispanic woman (height = 5 feet, 3 inches; weight = 160 pounds), who exhibited cellulitis 3 days after a car door was closed on her right hand. She was admitted to the hospital, where blood and wound cultures were found to be positive for methicillin-sensitive Staphylococcus aureus. She received 2 full days of nafcillin 2 g IV every 4 hours before being discharged to complete a 14-day course with dicloxacillin 500 mg PO 4 times daily (QID). Ten days after discharge, J.S. returned to the emergency department complaining of malaise, fever, diffuse rash, hematuria, and reduced urine output. The following laboratory values were significant:

BUN, 39 mg/dL
SCr, 2.3 mg/dL
WBC count, 18,500 cells/µL with 18% eosinophils

The urinalysis was positive for elevated specific gravity, WBC, RBC, eosinophiluria, and a FE_{Na} of 3%. What objective data suggest drug-induced AIN?

J.S.'s onset of symptoms suggests antibiotic-induced AIN. As illustrated by this case, the median onset of penicillin-induced AIN generally occurs 6 to 10 days after drug exposure. Hallmark symptoms of antibiotic-associated AIN include fever, macular rash, and malaise. Fever is present in nearly all patients with antibiotic-induced AIN, and rash occurs in 25% to 50% of patients. In contrast, NSAIDs, proton pump inhibitors, and rifampin are less commonly associated with rash, fever, eosinophilia, and the onset of AIN may occur several weeks to months or longer following drug exposure.[89,90] J.S.'s objective laboratory data that suggest AIN include azotemia, elevated SCr, proteinuria, cellular urinary sediment, eosinophilia, and eosinophiluria. Her FE_{Na} of 3% suggests intrinsic renal disease, and her eosinophiluria and eosinophilia indicate an immune-mediated allergic reaction. Drug-induced AIN is generally nonoliguric, but oliguria can develop in severe cases of AIN.

CASE 29-7, QUESTION 2: How should J.S.'s penicillin-induced AIN be treated?

The dicloxacillin should be stopped immediately because most patients recover normal kidney function once the offending agent is discontinued. Clindamycin or doxycycline may be chosen to finish the course of treatment for cellulitis. However, J.S. has completed 12 out of 14 days of antibiotic therapy and alternate agents would be optional. General supportive measures that maintain fluid and electrolyte balance are necessary. Renal recovery may take weeks to months. Corticosteroids have been used with variable results to shorten the duration of AKI, but no clinical guidelines have been developed to delineate when to administer them and for how long. Some clinicians prefer to administer prednisone 1 mg/kg for 7 days and then gradually taper the dose during the next several weeks. The response to corticosteroids may be delayed or absent in some patients. Dialysis may be needed in patients who are oliguric, but it is usually not required for those who are nonoliguric. The clinician should document J.S.'s allergic reaction to penicillins in her medical record, and not rechallenge the patient to antibiotics with similar chemical structures because repeated exposure is likely to result in similar reactions.

POSTRENAL ACUTE KIDNEY INJURY

Any condition that results in the obstruction of urine flow at any level of the urinary tract is termed postrenal AKI. Common causes of postrenal AKI are nephrolithiasis (stone formation), crystal formation, underlying malignancies of the prostate or cervix, prostatic hypertrophy, or bilateral ureter strictures. Conditions that result in bladder outlet obstruction (e.g., prostatic hypertrophy) are the most common causes of postrenal AKI. The onset of signs and symptoms is generally gradual; it often presents as decreased force of urine stream, dribbling, or polyuria. Drugs can also result in insoluble crystal formation in the urine and should be included in the differential diagnosis.

Table 29-7

Risk Factors for Nephrolithiasis

Low urine volume
Hypercalciuria
Hyperoxaluria
Hyperuricosuria
Hypercitruria
Chronically low or high urinary pH

Nephrolithiasis

Kidney stones generally consist of uric acid, cystine, struvite (also called magnesium ammonium phosphate or triple phosphate nephrolithiasis), and calcium salts. Of these, calcium stones are by far the most prevalent.[91]

Calcium nephrolithiasis constitutes approximately 70% to 80% of all kidney stones,[92] with calcium oxalate and calcium phosphate stones making up most of these. Genetic factors appear to play an important role in the development of calcium nephrolithiasis; the stereotypical patient is a man in his third to fifth decade of life. Other risk factors for developing calcium nephrolithiasis are low urine output, inadequate hydration (e.g., living in a hot climate and not drinking adequate fluids), hypercalciuria, hyperoxaluria, hypocitraturia, hyperuricosuria, and distal renal tubular acidosis (Table 29-7). Generally, more than one of these conditions are present simultaneously. The diagnosis and management of kidney stones are beyond the scope of discussion in this chapter. However, pharmacists can be instrumental in providing proper counseling on hydration and preventive measures.

CRYSTAL FORMATION

Crystal-induced AKI most commonly occurs as a result of acute uric acid nephropathy and following the administration of drugs or toxins that are poorly soluble or have metabolites that are poorly soluble in urine. Other drugs or toxins (e.g., ascorbic acid, ethylene glycol) may be metabolized to insoluble products such as oxalate, which are associated with precipitation of calcium oxalate crystals in the urine within the tubular lumen resulting in kidney injury.[92,93]

PRESENTATION AND TREATMENT

CASE 29-8

QUESTION 1: T.C., a 25-year-old male with a past medical history of schizophrenia, was seen in an outpatient clinic 4 days prior to admission where he was started on oral acyclovir 800 mg 5 times a day for a diagnosis of herpes zoster. He presents to the emergency department complaining of sharp flank pain, gross hematuria, and dysuria. Serum chemistries are ordered and are significant only for a BUN of 34 mg/dL and a SCr of 1.5 mg/dL, which are up from his baseline values of 7 and 0.9 mg/dL, respectively. A urine sample was obtained and visualized with microscopy. Birefringent needle-shaped crystals were seen on polarizing light microscopy. It was consistent with acyclovir-induced nephropathy. On questioning, he admits that he has not been drinking much fluid during the past week owing to a busy work schedule, and his urine volume has been markedly lower than usual. Which drugs can crystallize in the urine and cause AKI?

Table 29-8

Commonly Used Drugs that Cause Crystal-Induced Acute Kidney Injury

Acyclovir
Ciprofloxacin
Indinavir
Methotrexate
Sulfonamide antibiotics
Orlistat
Triamterene

Many commonly prescribed drugs are insoluble in urine and crystallize in the distal tubule (Table 29-8). Risk factors that predispose patients to crystalluria include severe volume contraction, underlying renal dysfunction, or acidotic or alkalotic urinary pH. In conditions of renal hypoperfusion, high concentrations of drug become stagnant in the tubule lumen. Drugs that are weak acids (e.g., methotrexate, sulfonamide antibiotics) precipitate in acidic urine; drugs that are weak bases (e.g., ciprofloxacin, indinavir, and other protease inhibitors) precipitate in alkaline urine. Patients with drug-related crystal-induced AKI are usually asymptomatic, and kidney injury is detected by an increased SCr. Occasionally, like T.C., patients present within 1 to 7 days after initiation of the offending drug with renal colic symptoms such as flank or abdominal pain, nausea, or vomiting. Urinalysis often reveals hematuria, pyuria, and crystalluria. The diagnosis is suggested by the appearance of crystals in the urine, the morphology of which depends upon the specific causative drug. Prevention of crystal-induced AKI is targeted at dosage adjustment for patients with underlying renal dysfunction, volume expansion to increase urinary output, and urine alkalization to enhance renal elimination of drugs that are weak acids or urine acidification to enhance renal elimination of drugs that are weak bases. Dialysis may be necessary in a small percentage of patients. With appropriate pharmacotherapy, crystal-induced AKI is usually reversible without long-term complications.[94]

SUPPORTIVE MANAGEMENT OF ACUTE KIDNEY INJURY

CASE 29-9

QUESTION 1: J.W. is a 75-year-old Native American man (height = 6 feet, 2 inches; weight = 200 pounds), who presents to the emergency room with shortness of breath and progressive worsening edema in both lower extremities. His medical history includes nephrotic syndrome secondary to diabetic nephrosclerosis, type 1 diabetes, hypertension, and chronic obstructive pulmonary disease. His surgical history includes a right-sided nephrectomy many years ago. His chronic medications are furosemide 80 mg PO twice a day, metolazone 10 mg PO once a day, lisinopril 5 mg PO once a day, diltiazem extended-release 120 mg PO once a day, albuterol, inhaler as needed, and subcutaneous 20 units insulin glargine at bedtime, and insulin aspart before meals. Vital signs are temperature 36.3°C, pulse 77 beats/minute, respirations 16 breaths/minute, and BP 179/86 mm Hg. Physical examination reveals periorbital edema, jugular venous distension at a 45-degree angle to the jaw, dullness to percussion halfway up the lungs bilaterally, and 4+ pitting edema in the extremities. Admitting laboratory tests reveal the following:

Sodium, 140 mEq/L
Potassium, 5.5 mEq/L

Chloride, 103 mEq/L
Bicarbonate, 19 mEq/L
Glucose, 249 mg/dL
BUN, 67 mg/dL
SCr, 5.2 mg/dL
Serum albumin, 2.0 g/dL
Spot urine albumin:creatinine ratio, 350 mg/g

Baseline renal function tests 1 month ago are BUN 45 mg/dL and SCr 3.0 mg/dL. J.W. is oliguric with a urine output of 10 mL/hour. The nephrologist wants to use supportive management of AKI by first optimizing diuretic therapy. If no increase in urine output occurs during the next several hours, then the patient will undergo RRT. What is the supportive management of AKI?

Despite years of study, no pharmacologic "cure" for AKI exists. Supportive management is therefore directed at preventing its morbidity and mortality. This is achieved by close patient monitoring; strict fluid, electrolyte, and nutritional management; treatment of life-threatening conditions such as pulmonary edema, hyperkalemia, and metabolic acidosis; avoidance of nephrotoxic drugs; and the initiation of dialysis or CRRT.

An assessment of volume status should be performed in all patients who present with AKI, since correction of volume depletion or volume overload may reverse or ameliorate AKI. The underlying cause dictates management of AKI. Treating the underlying cause is of extremely important. For example, prerenal AKI because of volume-depleted states, such as septic shock, requires administration of fluids and vasopressors to restore renal perfusion and increase urine output. On the other hand, diuretic administration for preload reduction to increase cardiac output would be required for prerenal AKI because of volume-overload states as in congestive heart failure.

As discussed earlier, diuretics currently have no role in preventing AKI progression or reducing mortality, but they can prevent complications, such as pulmonary edema. For edema, intravenous furosemide (e.g., 80–120 mg) is preferred because of its potency and pulmonary vasodilation properties. Oral furosemide therapy should be avoided because gut edema may limit its bioavailability. Torsemide and bumetanide are two other loop diuretics that have excellent oral bioavailability and are unaffected by gut edema. The dosage of diuretic needed is highly patient specific, especially in those with frank proteinuria, glomerulonephritis, or the nephrotic syndrome. Low serum albumin limits drug transport to the kidneys and thus limits diuretic effectiveness. In addition, furosemide is highly protein bound, and thus binds to filtered protein, which negates its pharmacologic effect on the kidneys. Combinations of loop and thiazide diuretics may be needed in patients with AKI if they become diuretic resistant. This combination acts synergistically to block sodium and water reabsorption in both Henle's loop and the distal convoluted tubule. Other alternatives include continuous loop diuretic infusions, such as furosemide 1 mg/kg/hour. The infusion rate should not exceed 4 mg/minute because these rates are associated with ototoxicity, especially when given in combination with aminoglycoside antibiotics. Close monitoring of serum bicarbonate, potassium, magnesium, and calcium is necessary when giving large doses of loop diuretics. Diuresis should aim for a weight loss of 0.5 to 1.0 kg/day. If diuretics fail to achieve the desired fluid overload reduction, dialysis or CRRT can be considered.

Hyperkalemia commonly occurs in patients with AKI because the kidneys regulate potassium homeostasis. It can be life threatening. It is prevalent in oliguric patients who are catabolic or have evidence of active cellular breakdown, such as rhabdomyolysis and tumor lysis syndrome. J.W. is mildly hyperkalemic, but his serum potassium may decrease after furosemide therapy. Management of hyperkalemia is discussed in Chapter 27, Fluid and Electrolyte Disorders. In cases of severe hyperkalemia in which conventional pharmacologic treatment is not feasible, or not working, emergency hemodialysis should be performed. Medications that can cause hyperkalemia such ACE-inhibitors, ARBs, or trimethoprim should be avoided.

Metabolic acidosis is a common manifestation of AKI because the kidneys are responsible for excreting organic acids. Other factors also contribute to severe acidosis among patients with AKI, who are often critically ill. For example, patients with AKI because of septic shock, trauma, and multi-organ failure often have increased production of lactic acid or ketoacids. J.W.'s serum bicarbonate concentration reveals slight acidemia that does not require correction at this time. Commonly used treatments for metabolic acidosis include bicarbonate administration and dialysis. Bicarbonate therapy may be administered as first corrective therapy, in non–life-threatening and non–fluid-overloaded metabolic acidosis. Severe metabolic acidosis ($pH < 7.1$) in the presence of anuria or oliguria and a fluid overload state should be corrected with dialysis, since worsening volume overload can occur with the administration of sodium bicarbonate therapy.

Uremia can interfere with platelet aggregation resulting in hemorrhagic diathesis. Uremic patients display increased bleeding sensitivity to aspirin compared to normal patients taking aspirin. Patients with uremia and major hemorrhagic bleed may benefit from using desmopressin (dDAVP) 0.3 mcg/kg intravenously or subcutaneously for one or two doses. Desmopressin produces a dose-related increase in von Willebrand factor VII and t-PA levels; this shortens activated antithromboplastin time (aPTT) as well as bleeding time. The improvement in bleeding time typically begins within about 1 hour to 4 to 8 hours. Tachyphylaxis typically develops after the second dose. Other modalities that can improve platelet function and reduce bleeding in an AKI patient include dialysis, conjugated estrogens, and cryoprecipitate.[95]

Clinicians should closely monitor the patient's vital signs (e.g., weight, temperature, BP, pulse, and respirations) several times per day. The patient's volume status should be assessed daily, and all fluids should be adjusted based on laboratory chemistries to detect fluid and electrolyte abnormalities, urine output, and gastrointestinal and insensible losses. Pharmacists should pay attention to nutritional support for patients with AKI to provide adequate amounts of energy, protein, and nutrients, while being sensitive to the electrolytes, acidosis, and volume balance issues. The patient's medication profile should be reviewed daily to assess for appropriate dosage adjustment in renal dysfunction. Because estimation of ClCr is difficult in patients with changing renal function, therapeutic drug monitoring should be performed when using drugs with narrow therapeutic indices. When possible, nephrotoxic drugs should be avoided, but this may be difficult in patients who are septic or hypotensive and require nephrotoxic antibiotics and vasopressors. Preventive measures to reduce the likelihood of AKI should be used, such as monitoring volume status to ensure adequate renal perfusion, using dosing strategies or products that are associated with less nephrotoxicity, and avoiding drug therapy combinations that enhance nephrotoxicity (e.g., NSAID, aminoglycosides).

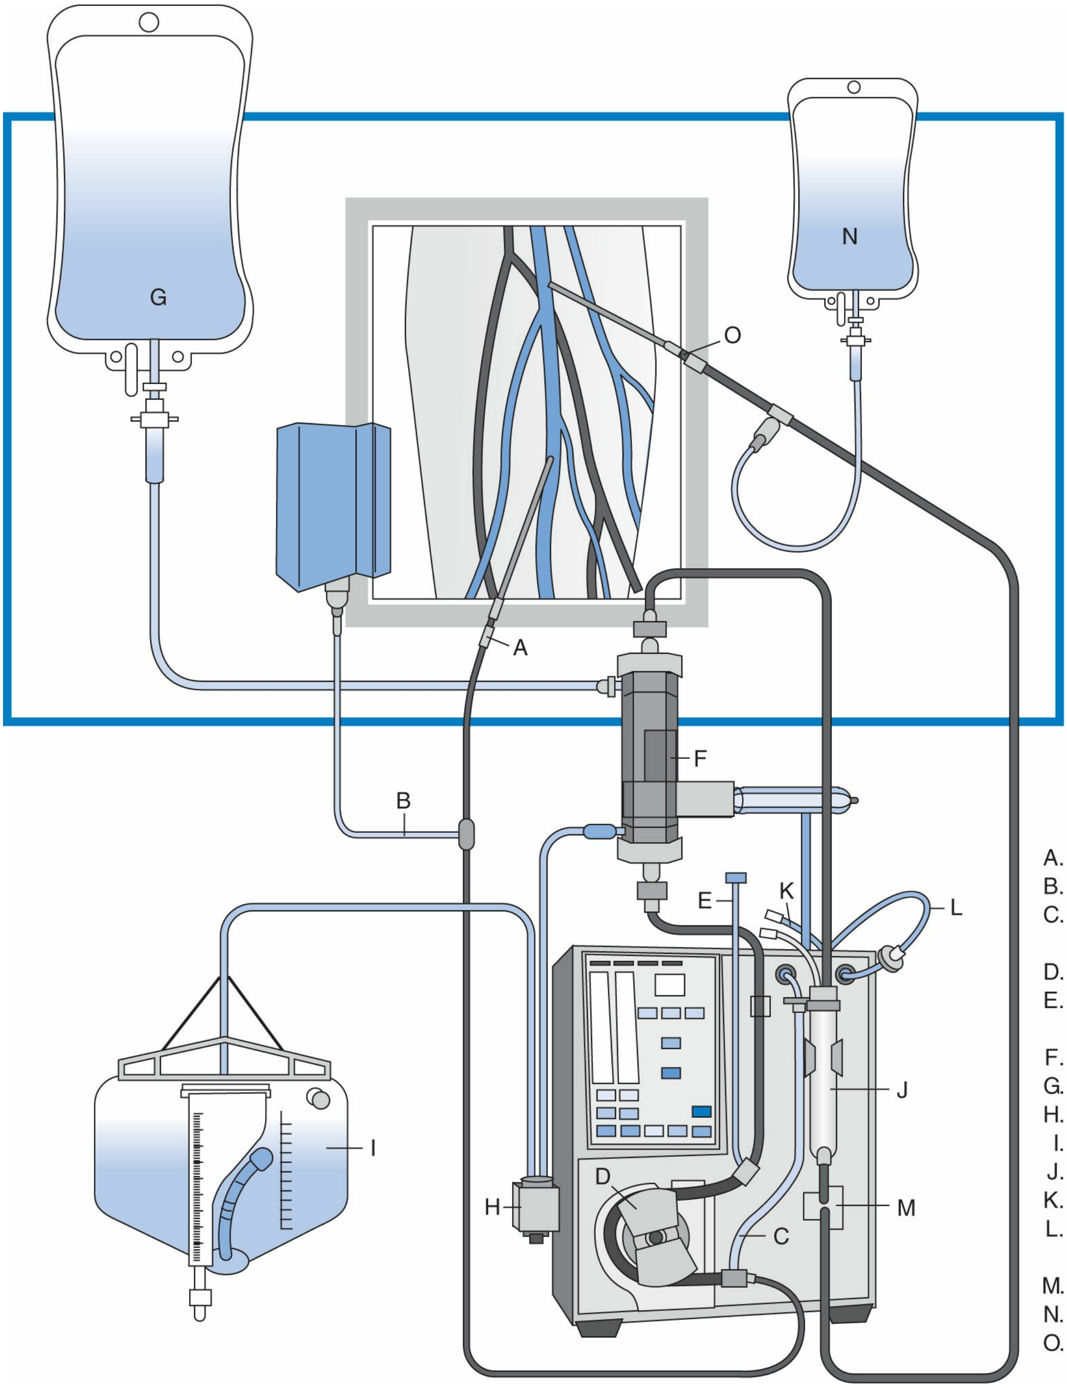
Extracorporeal Continuous Renal Replacement Therapy

RRT is not always indicated in AKI. The A-E-I-O-U mnemonic is used to help remember the indications for RRT, where ‘A’ stands for intractable refractory acidosis, ‘E’ refers to electrolyte abnormalities, specifically potassium with EKG changes, ‘I’ refers to ingestion of toxins such as salicylates and ethylene glycol, ‘O’ stands for fluid overload causing pulmonary edema, and ‘U’ refers to symptomatic uremia with confusion, platelet dysfunction and severe bleed, and seizures.

The risks associated with RRT are hypotension, arrhythmias, vascular access placement complications, and increased risk of ESRD. Hence, the decision to initiate RRT has to be carefully discussed. The timing of optimal initiation of RRT is also lacking. Early initiation may decrease mortality in critically ill patients and the need for permanent RRT at discharge.[96]

RRT can be divided into intermittent hemodialysis or CRRT, such as continuous peritoneal dialysis or extracorporeal CRRT. The decision to use one versus the other is most often decided by the nephrologist’s experience and comfort level. CRRT may be preferred in patients who are hemodynamically unstable or requiring vasopressor support. Extracorporeal CRRT differs from peritoneal and hemodialysis in its mechanism of solute removal; dialysis modalities rely primarily on solute diffusion across a semipermeable membrane, whereas CRRT relies primarily on convective ultrafiltrate production. This discussion will be limited to extracorporeal (hemofilter membrane is outside of the body) CRRT therapies (see Chapter 30, Renal Dialysis, for a complete overview of peritoneal and hemodialysis).

Not all extracorporeal CRRT is alike[97]; many variations exist and include modalities such as continuous arteriovenous hemofiltration (now obsolete), continuous venovenous hemofiltration (CVVH), continuous venovenous hemodialysis (CVVHD), and continuous venovenous hemodiafiltration (CVVHDF; Fig. 29-5). Differences among these modalities are illustrated in Table 29-9. Drug dosing can be difficult in patients receiving these therapies, especially in those who are undergoing both dialysis and hemofiltration modalities (i.e., CVVHDF).



A. Blood exiting the body
B. Heparin infusion
C. Arterial pressure monitor (prefilter pressure)
D. Blood pump
E. Saline infusion line (saline not shown here)
F. Filter
G. Dialysate
H. Blood leak detector
I. Graduated collection device
J. Air and foam detector
K. Syringe line
L. Venous pressure monitor (postfilter pressure)
M. Clamp
N. Replacement fluid
O. Blood returns to body

Figure 29-5 Schematic of continuous venovenous hemodiafiltration (CVVHDF). Blood is accessed by a dual-lumen catheter in a central vein and is pumped through the extracorporeal circuit by a roller blood pump. The blood pump maintains a constant hydrostatic pressure to create ultrafiltration, even in hypotensive conditions. Dialysate flows in a countercurrent direction to blood flow. Patients receiving CVVHDF are most often in the intensive care unit and often receive concomitant parenteral nutrition.

Table 29-9

Comparison of Extracorporeal Continuous Renal Replacement Therapies

	Continuous Venovenous	Continuous Arteriovenous	Continuous Venovenous	Continuous Venovenous

Parameter	Hemofiltration (CVVH)	Hemofiltration (CAVH)	Hemodialysis (CVVHD)	Hemodiafiltration (CVVHDF)
Volume control in hypotensive patients	Good	Variable	Good	Good
Solute control in highly catabolic patients	Adequate	Inadequate	Adequate	Adequate
Blood flow rates in hypotensive patients	Adequate	Poor	Adequate	Adequate
Ease of drug dosing	Published recommendations	Difficult	Difficult	Difficult
Dialytic solute clearance	None	None	Moderate	Moderate
Convective solute clearance	Good	Good	Minimal	Moderate
Corresponding GFR (mL/minute)	15–17	10–15	17–21	25–26
Blood pump required	Yes	No	Yes	Yes
Replacement fluid required	Yes	Yes	Yes	Yes
Pharmacy expense	High	High	High	High

GFR, glomerular filtration rate.

Estimating Drug Removal

CASE 29-9, QUESTION 2: Are there ways to calculate drug removal in extracorporeal CRRT modalities?

Recent reviews provide an excellent background on dosing drugs in patients receiving CRRT.[9,32,98–100] The principles for drug removal in hemofiltration are basically identical with those for removal in hemodialysis. Drug removal during CRRT may occur by convection, diffusion, and adsorption. Convection and diffusion have the greatest influence on drug removal. Drug removal is inversely proportional to the percentage of drug that is protein bound. If a drug is >80% plasma protein bound, little will be removed. This principle holds true for convection and diffusion. Ultrafiltration and dialysis flow rates (UFR/DFR) also affect drug clearance. Because CRRT uses highly permeable membranes, the molecular weight (MW) of most drugs has little impact on overall clearance. During convection, clearance of an unbound drug can be dramatic since CVVH can remove easily compounds with MW <15,000 Da. The impact of MW on drug removal during CVVHD is greater than the impact seen during CVVH. Solute clearance during CVVHD is dependent on diffusion and given that diffusion is inversely proportional to MW, the greatest impact is seen with drugs having a low MW <500 Da. Many drugs have low MW and hence CVVHD can impact their removal significantly. Clearance during CVVH is accomplished through the process of convection. The ultrafiltrate produced is replaced either in part or completely. Clearance of unbound drugs during CVVH can be dramatic and dose adjustments are required to prevent underdosing.

The sieving coefficient (SC) of a drug is the non–protein-bound fraction of the drug that is in plasma. SC ranges from 0 to 1 (zero representing no convective clearance). For example, a SC of 0.8 means that 80% of the drug is unbound in plasma. Drug SC can be obtained from the literature or by measuring concentrations simultaneously in the prefilter blood and ultrafiltrate. The ratio of the ultrafiltrate concentration to plasma concentration is the SC. Drug clearance can be calculated by multiplying the SC by the ultrafiltration rate. For example, if a patient is receiving CVVH at an ultrafiltration rate of 1 L/hour, and he or she is receiving vancomycin (which has an SC of 0.8) 1 g/day, the vancomycin clearance while receiving CVVH is 0.8 × 1,000 mL/hour = 800 mL/hour or 13 mL/minute.

Calculating drug clearance is much more difficult in hemodiafiltration modalities (CVVHDF) because both convection and diffusion account for drug clearance, and it is difficult to predict drug clearance precisely. The use of SC can be useful for small-molecular-weight drugs, but the accuracy declines with larger drug molecules, such as vancomycin. When possible, therapeutic drug monitoring should be performed to maintain therapeutic concentrations and to maximize drug therapy.

Drug references such as Drug Prescribing in Renal Failure provide useful guidelines in a concise tabular format.[101]

Renal Dialysis

Myrna Y. Munar

	CORE PRINCIPLES	CHAPTER CASES
1	End-stage renal disease (ESRD) occurs when there is progressive loss of kidney function over a period of months to years to the point where the kidneys can no longer remove wastes; concentrate urine; maintain acid–base homeostasis; and regulate fluid, electrolytes, and other important body functions.	**Case 30-1 (Question 1)**
2	Dialysis is a process that facilitates the removal of excess water and solutes from the body, both of which accumulate as a result of inadequate kidney function. Solutes from the blood are removed through diffusion and convection. Accumulated water is removed by ultrafiltration.	**Case 30-1 (Question 1),** **Figure 30-1**
3	The ability of a dialyzer to remove solutes and water is determined by its composition, pore size, surface area, and configuration.	**Case 30-1 (Question 1),** **Figure 30-1**
4	Dialysate is an electrolyte solution that simulates plasma. The concentration of electrolytes in dialysate can be manipulated to control the diffusion of electrolytes from the blood into dialysate to maintain homeostasis. Metabolic acidosis is controlled with the addition of bicarbonate to dialysate.	**Case 30-1 (Question 1),** **Figure 30-1**
5	Different types of vascular access are available: arteriovenous (AV) fistula, AV graft, and double-lumen or tunneled catheters. An AV fistula is preferred because of its longer survival rates and low rates of complications.	**Case 30-1 (Question 2)**
6	Anticoagulation is necessary during hemodialysis (HD) to prevent blood from clotting in the extracorporeal circuit. Several methods have been used to provide adequate anticoagulation without increasing the risk of bleeding.	**Case 30-1 (Questions 3–5)**
7	Complications can arise during HD. The most common complications are hypotension and muscle cramps. Graft thrombosis and graft infection are common chronic complications.	**Case 30-1 (Questions 6–9),** **Case 30-2 (Questions 1–2)**
8	Continuous ambulatory peritoneal dialysis is performed by instilling sterile dialysate into the peritoneal cavity through a surgically placed resident catheter. The solution dwells within the cavity for 4 to 8 hours, and then it is drained and replaced with a fresh solution. This process of fill,	**Case 30-3 (Question 1),** **Figure 30-2**

dwell, and drain is performed 3 to 4 times during the day, with a longer dwell overnight.	
⑨ The process of peritoneal dialysis (PD) is similar to HD; in this process, however, the peritoneal membrane covering the abdominal contents serves as an endogenous dialysis membrane, and the vasculature embedded in the peritoneum serves as the blood supply. Fluid is removed by manipulating the dextrose concentration in dialysate to control the osmotic pressure gradient for fluid removal.	**Case 30-3 (Question 1), Figure 30-2**
⑩ The most significant complication among patients having PD is peritonitis. Empiric antibiotics can be administered by the intraperitoneal (IP) route and must cover both gram-positive and gram-negative organisms.	**Case 30-3 (Questions 2, 4)**
⑪ Other medications can be administered IP. Heparin can be added to dialysate to prevent fibrin clots from forming and obstructing outflow from the peritoneal cavity. Regular insulin can be administered IP to patients with diabetes.	**Case 30-3 (Questions 3, 7)**
⑫ Prevention of catheter exit-site infections (and thus peritonitis) is the primary goal of exit-site care. Routine care consists of hand cleansing with antiseptics or antibacterial soap before touching the exit site, washing the exit site daily with antibacterial soap, and use of antimicrobial creams around the exit site.	**Case 30-3 (Questions 5, 6)**

End-stage renal disease (ESRD) occurs when there is progressive loss of kidney function over a period of months to years to the point where the kidneys can no longer remove wastes, concentrate urine, maintain acid–base homeostasis, and regulate fluid and electrolytes and other important body functions. ESRD is classified under stage 5 chronic kidney disease (CKD), which refers to patients with an estimated glomerular filtration rate (eGFR) less than 15 mL/minute/1.73 m^2, or those requiring dialysis or transplantation.[1,2] Demographic characteristics of ESRD population are based primarily on data from the Centers for Medicare and Medicaid Services, because patients with ESRD are eligible for Medicare benefits. Coverage for ESRD began in 1972, when Congress enacted the End-Stage Renal Disease Program as an amendment to Medicare. Data from the ESRD program are reported annually by the United States Renal Data System. According to the 2014 Annual Report, diabetes and hypertension continue to be leading causes of ESRD.[3] Patients aged 45 years and older account for the largest segment of the ESRD population. Racial differences in the prevalence of ESRD persist. While prevalence of ESRD in Native Americans has declined since 2000, prevalence rates remain much higher in Blacks/African Americans than in other racial groups, at nearly twofold higher than Native

Americans, 2.5-fold higher than Asians, and fourfold higher than Whites.[3]

In 2012 there were 636,905 prevalent cases of ESRD in the United States, an increase of 3.7% from the previous year. Of these, 402,514 patients were treated by hemodialysis (HD), 40,605 were on peritoneal dialysis (PD), and 17,305 kidney transplantations were performed.[3] The number of kidney transplants has remained stable since 2005. Recipients living with a functioning graft continue to grow, reaching 186,303 in 2012 reflecting a 3.6% increase from 2011. However, the shortage of donor kidneys and the existence of patients with ESRD, who are unacceptable transplant recipients, sustain the demand for dialysis. Kidney transplantation is further discussed in Chapter 34, Kidney and Liver Transplantation.

The two primary modes of dialysis therapy are HD and PD. Both HD and PD were developed as methods for the removal of metabolic waste products across a semipermeable membrane.

HD is an extracorporeal (dialysis membrane is outside of the body) process, whereas PD uses the patient’s peritoneal membrane for the clearance of water and solutes. Variations of PD include continuous ambulatory peritoneal dialysis (CAPD) and automated peritoneal dialysis (APD), an increasingly common modality that permits greater patient flexibility with dialysis at home. Among the 443,119 dialysis patients in the United States, 91% undergo HD.[3] Most of these patients receive dialysis 3 times a week in a center designed primarily for stable, ambulatory patients at either a hospital-based or a free-standing dialysis facility. Home HD accounts for less than 1% of dialysis patients. Patients having PD are also managed through dialysis centers for routine care, although less often than patients on HD. The most frequent form of dialysis in children is APD. Several factors are considered in the selection of the type of dialysis for each patient. Often, the overriding consideration is the suitability of the procedure for the patient’s lifestyle. A patient who needs flexibility and freedom from a rigid schedule may prefer PD versus HD to avoid the necessity of being at a dialysis center 3 times weekly for a 3- to 4-hour dialysis treatment. Other considerations include the availability of a vascular access site for HD, a patient’s ability to perform self-care for dialysate exchanges with PD, or the capability of the patient, parent, or caregiver to carry out APD at home.

Without dialysis or transplantation, patients with ESRD will die from the metabolic complications of their renal failure. Survival on dialysis has improved over the years. Since 1993, mortality rates have fallen across all renal replacement modalities with a 28% reduction for HD patients, 47% reduction for PD patients, and 51% reduction for transplant patients.[3] While these rates are encouraging, only 54% of HD patients and 65% of PD patients survive beyond 3 years after ESRD onset. All-cause mortality rates are 6.1 to 7.8 times higher for dialysis patients compared to the general population, and highest in the second and third months of dialysis. Dialysis patients are expected to live one-third as long as people of the same age in the general population. Transplant patients live longer with an estimated lifetime that is 83% to 87% of the general population.

The rapid growth of the number of patients having dialysis calls attention to the need for practitioners who understand the processes and therapies for these patients. This chapter addresses the fundamental clinical aspects of both HD and PD, including principles, complications, and management. Throughout the chapter, reference will be made, when appropriate, to the Kidney Disease Outcomes Quality Initiative (K/DOQI) clinical practice guidelines developed by the National Kidney Foundation.[4–6]

HEMODIALYSIS

Principles and Transport Processes

Dialysis is a process that facilitates the removal of excess water and toxins from the body, both of which accumulate as a result of inadequate kidney function. During HD, a patient’s anticoagulated blood (circulated to the dialyzer from a vein in the arm) and an electrolyte solution that simulates plasma (dialysate) are simultaneously perfused through a dialyzer (artificial kidney) on opposite sides of a semipermeable membrane. Solutes (e.g., metabolic waste products, toxins, potassium, and other electrolytes) are removed from the patient’s blood by diffusing across concentration gradients into the dialysate. The rate of removal of various solutes from the blood is a function of blood and dialysate flow rates through the dialyzer, relative concentration of each solute in the blood and dialysis solution (thus determining their concentration gradients across the membrane), physical characteristics of the dialysis membrane (e.g., total available surface area, thickness, and pore size), and properties of the solute being removed (e.g., molecular size in daltons, molecular weight, volume of distribution, and protein binding). Because blood and dialysate flow in opposite directions through the dialyzer, the concentration gradient for each solute across the membrane is amplified (Fig. 30-1). This principle is defined in greater detail in the Dialyzer Characteristics section.

Figure 30-1 Hemodialysis system. **(A)** Blood from an artery is pumped into **(B)**, a dialyzer where it flows through the cellophane tubes, which act as the semipermeable membrane (inset). The dialysate, which has the same chemical composition as the blood except for urea and waste products, flows in around the tubules. The waste products in the blood diffuse through the semipermeable membrane into the dialysate. Adapted with permission from Smeltzer SC, Bare BG. Textbook of Medical-Surgical Nursing. 9th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2000.

Solutes from the blood are removed through diffusion and convection. Diffusion is the process whereby the molecule moves across its concentration gradient by passing through pores in the dialysis membrane.[7] Once the concentration of a solute reaches equilibrium on both sides of the membrane, the net movement is zero because the rate of movement from the blood to dialysate compartment is equal to the rate from the dialysate to the blood compartment. For most substances, equilibrium is not achieved, either because the blood and dialysate flow rates are too rapid or the molecule is too large to easily move through the pores.

Accumulated water is removed by the process of ultrafiltration. A controlled pressure difference across the semipermeable membrane permits water movement through the membrane pores, carrying solute into the dialysate, thereby further enhancing solute removal. Flux is the rate of water transfer across the dialyzer. Convection is the process that removes toxins and other dissolved solutes during dialysis through the ultrafiltration of plasma water from the blood compartment. The removal of solutes by convection during ultrafiltration generally is small relative to their elimination through diffusion.

DIALYZER CHARACTERISTICS

Dialyzers are characterized by many factors, such as membrane composition, size, and ability to clear solutes. Their primary component is the dialysis membrane, which is made of cellulose (e.g., cuprammonium cellulose), substituted cellulose (e.g., cellulose acetate, cellulose triacetate), cellulosynthetic, or synthetic polymer (e.g., polysulfone, polyacrylonitrile, and polymethylmethacrylate).[8] Membranes differ not only by composition but also by surface area, thickness, and configuration within the dialyzer. The most common configuration is the hollow fiber dialyzer, whereby the membrane is formed as thousands of hollow fibers that run the length of the dialyzer. Blood flows through the fibers and the dialysate flows in the space surrounding the fibers within the dialyzer cartridge. The result is an extremely large surface area for diffusion, which is functionally increased further by the movement of blood and dialysate in opposite directions, so that equilibrium is never fully achieved. Another, less common design is the parallel-plate configuration, whereby blood and dialysate flow between alternating sheets of the membrane.

Functionally, dialysis filters can be differentiated based on their ability to remove solutes and water. The flux of water across the dialyzer is correlated with the clearance of middle molecular weight molecules. Thus, dialyzers are characterized as low-flux or high-flux based on pore size and ability to remove small versus large molecules. One method of categorizing and comparing efficiency (flux) of dialyzer units is to compare the relative in vitro and in vivo clearance rates of marker solutes of varying molecular size. This information is usually printed on the outside of the dialyzer or in the package insert (specification

---

chart) for the dialyzer. For example, urea (molecular size, 60 Da) is a marker of small-molecule transport across the dialysis membrane. Urea (found in the blood as blood urea nitrogen [BUN]) distributes freely throughout body water and is cleared rapidly by HD, even when using standard low-flux dialyzers. Because the pore size of most dialyzer membranes is large enough to allow this small molecule to freely diffuse, the rate-limiting step for the removal of urea is blood flow through the dialyzer. A larger molecule, vitamin B_{12} (molecular size, 1,355 Da), has also been used as a measure of dialysis efficiency. Because vitamin B_{12} is too large to easily cross through the pores of conventional dialysis membranes, its dialysis clearance is less dependent on blood flow than urea. Instead, the overall removal of vitamin B_{12} depends more on the type of membrane (i.e., thickness and pore size) and the duration of dialysis. The clearance of β_2-microglobulin, an even larger molecule than vitamin B_{12} (molecular size, 11,800 Da), has been used to characterize the flux of a dialyzer.[4,8] High-flux dialyzers are defined as providing β_2-microglobulin clearances of at least 20 mL/minute.[4] β_2-microglobulin clearance, however, is not consistently reported in all dialyzer specification charts. High-flux membranes have larger pores and are able to clear larger molecules (e.g., middle molecules such as β_2-microglobulin and leptin) and drugs (e.g., vancomycin or vitamin B_{12}, with molecular weights in the range of 1,000–5,000 Da) more effectively than low-flux membranes with smaller pores. High-flux membranes also have a greater permeability to water, as reflected in a KUf value (to be defined later) of more than 10 mL/hour/mm Hg.

Similarly, molecular weight of drugs is a predictor of dialysis clearance. At a molecular weight of less than 500 Da (e.g., aminoglycosides and theophylline), dialyzability is expected to be high. For these drugs, the actual amount dialyzed will vary based on protein binding (i.e., amount of unbound drug available to cross the dialysis membrane), volume of distribution (Vd) (i.e., a large Vd indicates a relatively small amount of drug will be available in the blood for dialysis), blood flow rate through the dialyzer, dialysis flow rate, and dialyzer surface area. Drugs with a molecular weight between 500 and 1,000 Da (e.g., morphine and digoxin) are less well dialyzed. For digoxin, a greater problem is its large Vd and relatively low serum concentrations. Even if the drug in the blood is effectively removed, tissue-bound drug will quickly redistribute back into the blood as soon as dialysis is completed, a phenomenon known as rebound. Finally, large molecular weight drugs, such as vancomycin, are poorly dialyzed by conventional dialyzers, but they may be removed using high-flux techniques described later in this chapter.

The efficiency of a dialyzer is also a function of its surface area. High-efficiency membranes generally have a large surface area and are able to clear large quantities of small molecules, such as urea. High-efficiency dialyzers can also have small or large pores, resulting in low or high clearance of larger molecular weight solutes. Membranes also differ in their degree of biocompatibility. When free hydroxyl radicals on the surface of cellulose membranes come in contact with blood, the complement pathway is activated and proinflammatory cytokines are produced, which can lead to hypotension, fever, and platelet activation in patients.[9] Use of these membranes has declined. The free hydroxyl groups can be substituted with other chemical structures, such as acetate, to improve biocompatibility. Complement activation and cytokine release occur to a much lesser extent with substituted cellulose or cellulosynthetic membranes, and least of all with synthetic membranes made from plastics.

A typical package insert for a dialyzer will provide information on the clearance of various molecules (e.g., urea, creatinine, phosphate, and vitamin B_{12}). Urea clearance has become a common measure of comparison for membranes; however, clearance also depends on other factors, such as blood and dialysate flow rates. A more standard measure for comparison is KoA_{urea}, the mass transfer area coefficient for urea. Based on the urea clearance data from the package insert, KoA_{urea} can be estimated based on blood flow. Using this information, the dialysis prescription can be individualized to provide a specified dose of dialysis for the patient.

Patients having chronic HD typically are dialyzed for 3 to 4 hours, 3 times a week, either Monday-Wednesday-Friday or Tuesday-Thursday-Saturday. During the interdialytic period, fluids ingested and produced through metabolic processes are retained in the patient. Although patients generally are on fluid-restricted diets, accumulation of 1 to 5 L of fluid (translating into 1- to 5-kg weight gain) between sessions is common and must be removed during the dialysis treatment.

BLOOD AND DIALYSATE FLOW

Although small-molecule clearance is highly dependent on blood flow, the relationship is not strictly linear. Increased blood flow yields a less than proportional response in urea clearance.[10] This is likely because of an insufficient time for equilibration to occur between the blood and dialysate compartments as well as a greater membrane resistance to diffusion from an increased stagnant layer. A typical blood flow rate for dialysis is 400 to 500 mL/minute, but it is dependent on the vascular access site and the cardiovascular status of the patient. Some patients are not able to tolerate this rate, and a lower blood flow rate may be necessary. Dialysate flow rates generally are 500 mL/minute and can be increased to 800 mL/minute for high-flux dialysis, which will increase urea clearance by approximately 10%.[11]

CASE 30-1

QUESTION 1: R.W., a 55-year-old man with stage 4 CKD as a result of poorly controlled hypertension, presents to the renal clinic for reassessment of his kidney function. He is 70 inches tall and weighs 70 kg. Since his last visit 3 months ago, his creatinine clearance (ClCr) has decreased from 22 to 12 mL/minute and the BUN has increased to 89 mg/dL. The serum potassium (K) is 4.8 mEq/L and HCO_3 is 17 mEq/L. He has selected HD as his form of therapy until a suitable donor kidney is available and is expected to begin dialysis within the next 1 to 3 months. When he begins dialysis, he will be dialyzed 3 times a week for 4 hours each treatment, using a Fresenius F-160 dialyzer, with blood and dialysate flows of 400 and 500 mL/minute, respectively, and bicarbonate-containing dialysate. What characteristics of the Fresenius F-160 dialyzer make it a good choice for R.W.? What determines the composition of the dialysate?

The Fresenius dialyzer is a high-flux dialyzer as described previously. This polysulfone membrane is a synthetic membrane with larger pore sizes than conventional cellulose membranes. The F-160 has a KUf (the ultrafiltration coefficient [volume of water removed/mm Hg across the membrane per hour of dialysis]) of 45 mL/mm Hg/hour, indicating a high ultrafiltration capability; an in vitro KoA_{urea} of 1,064, a measure of dialyzer efficiency for urea removal; urea clearance of 266 mL/minute at a blood flow of 300 mL/minute; and a surface area of

1.5 m^2.[8] This information can be located in the product literature from the manufacturer or summary tables from common dialysis references.[8] These data are used to individualize the dialysis prescription for a patient.

DIALYSATE COMPOSITION

Dialysate composition usually is standardized within certain limits of electrolyte content, yet allows for individualization as necessary. Water is obtained through the public water system, which then undergoes treatment by reverse osmosis, followed by ion exchange with activated charcoal to remove contaminants, such as aluminum, copper, and chloramines, as well as bacteria and endotoxins.[12] The dialysate solution does not require sterilization because the dialysis membrane separates the blood and dialysate compartments. Nevertheless, pyrogen reactions may occur, and a greater risk may exist with high-flux membranes because of the increased pore size.

Table 30-1

Electrolyte Composition of Hemodialysis and CAPD Dialysate Solutions

Solute	Hemodialysis (mEq/L)	CAPD (mEq/L)
Sodium	135–145	132
Potassium	0–4	0
Calcium	2.5–3.5	3.5
Magnesium	0.5–1.0	1.5
Chloride	100–124	102
Bicarbonate	30–38	
Lactate		35
pH	7.1–7.3	5.5

CAPD, continuous ambulatory peritoneal dialysis.

The final dialysate solution is prepared in the dialysis machine by proportioning a dialysate concentrate with the purified water, resulting in a final product, which typically contains those elements listed in Table 30-1. By adjusting electrolyte concentration in the dialysate, the efficiency of dialysis for particular chemicals can be manipulated. For example, if the patient is hyperkalemic, the dialysate contains a low concentration of potassium for diffusion of potassium from blood into dialysate. On the other hand, if the patient is normokalemic at the start of dialysis, the potassium concentration of the dialysate is set at a normal physiologic concentration to minimize flux of this electrolyte across the membrane. If the concentration of a solute is higher in the dialysate than in the blood, the net movement will be into the blood, not out. Metabolic acidosis, which is associated with ESRD because of an inability to excrete the daily obligatory load of acid, is controlled with the addition of bicarbonate buffer to the dialysate solution. Before delivery, dialysate is heated to 37°C to maintain body temperature and avoid hemolysis, which can occur with excessive heating. Dialysate is also deaerated under vacuum to remove dissolved air from the solution.

Vascular Access

CASE 30-1, QUESTION 2: To achieve a sufficient blood flow for dialysis, R.W. must have a vascular site for chronic access. What are the options for chronic vascular access in R.W.?

A permanent vascular access site provides easy access to high blood flow, which cannot be achieved through routine venipuncture of superficial veins. Different types of vascular access are available: arteriovenous (AV) fistula made by joining an artery and vein in the arm, AV graft, a soft tube made of polytetrafluoroethylene to join an artery and vein in the arm, and a double-lumen or tunneled, cuffed catheter placed in a large vein usually in the neck. AV fistulas and grafts are placed in the nondominant arm. Ideal vascular access delivers blood flow rates necessary for chronic HD, has a long period of use, and has a low rate of complications (e.g., infection, stenosis, thrombosis, aneurysm, and limb ischemia).

An AV fistula is created surgically by subcutaneous anastomosis of an artery to an adjacent vein. The AV fistula may not be suitable for patients with poor vasculature, such as elderly patients or those with diabetes, atherosclerosis, or small vessels. The K/DOQI guidelines for vascular access advocate placement of a fistula at the location of the wrist (radial-cephalic), or secondarily the elbow (brachial-cephalic), as the preferred vascular access sites. Once created, vascular access requires time to mature before it can be used for HD. The fistula should preferably be created 3 to 4 months before its intended use to allow the vein to mature. The graft can be used soon after insertion, although 2 weeks will allow for healing at the anastomosis sites and may prolong patency. AV fistulas fail to mature at a higher rate than grafts; however, grafts require fourfold higher interventions per year (elective angioplasty, thrombectomy, or surgical revision) to maintain long-term patency for HD.[13] Central venous catheters are discouraged for chronic vascular access because of high rates of infection and occlusion.

During the dialysis procedure, one needle or catheter is placed into the fistula site to deliver blood to the dialyzer. This is often referred to as the “arterial line” to the dialyzer. Blood exiting the dialyzer is returned back to the patient’s fistula site through a second catheter and needle, referred to as the “venous line” from the dialyzer.

If R.W. has adequate vasculature, a fistula should be created for chronic access. Vascular access is critical for chronic HD and often has been labeled the Achilles’ heel of dialysis therapy. Complications associated with vascular access are a significant problem in patients having chronic HD. The most common is thrombosis, usually the result of venous stenosis.[6] If not treated, thromboses will result in loss of the access. Access-related complications are a major cause of hospitalization and, therefore, attention to these problems is important both clinically and economically.

ANTICOAGULATION

CASE 30-1, QUESTION 3: Recommend a reasonable anticoagulation regimen for R.W. with the initiation of his HD. What are alternatives for patients at high risk for bleeding?

Most patients undergoing HD are anticoagulated with IV heparin during the dialysis treatment. Anticoagulation is necessary to prevent blood from clotting in the extracorporeal circuit. Several methods have been used in an attempt to provide adequate anticoagulation without increasing the risk of bleeding. Approaches include the administration of heparin in adequate quantities to anticoagulate the patient during the dialysis procedure by either intermittent bolus injections or an initial bolus followed by a continuous infusion.[14] Modern HD delivery systems have incorporated heparin infusion devices that can be programmed to provide the desired infusion rate during dialysis.

With no evidence of a bleeding disorder, recent surgery, or other risk factors for heparin anticoagulation, therapy should be initiated with a 2,000-unit bolus of IV heparin 3 to 5 minutes before initiation of dialysis, followed by an infusion of 1,200 units/hour.[14] The target activated clotting time (ACT) is 40% to 80% above the average baseline for the dialysis unit (e.g., 200–250 seconds, for normal values of 120–150 seconds). The clinician should monitor for signs of bleeding and measure the ACT at 1-hour intervals during dialysis. Heparin should be discontinued 1 hour before the end of dialysis to prevent excessive bleeding after dialysis. Using these standard doses, the estimated elimination half-life for heparin is approximately 50 minutes, and it should have a linear dose–response relationship within the target ACT.[14]

Patients at increased risk of bleeding include those who have had recent surgery, retinopathy, gastrointestinal bleeding, and cerebrovascular bleeding. For these patients, the goal is to prevent clot formation within the dialysis circuit as well as to minimize the risk of active bleeding. This may be accomplished by using “minimal-dose” heparin (tight ACT control), or even heparin-free

---

anticoagulation. The minimal-dose heparin approach individualizes therapy to achieve ACT values 40% above baseline after an initial bolus of 750 units.[14] The ACT is measured 3 minutes after the bolus dose, which should allow for vascular distribution of the heparin to be complete. If the goal ACT level is not achieved, repeat bolus doses of heparin can be administered at a dose that is adjusted based on the expectation of a linear response. For example, if the first dose of 750 units reaches 75% of the ACT goal, an additional 250 units would be appropriate for the second dose. Similarly, the initial heparin maintenance infusion rate of 600 units/hour can be modified by monitoring the ACT at 30-minute intervals. Adjustments in the infusion rate should be proportionate to the bolus dose needed to maintain the ACT at 40% above baseline. Samples collected for determination of ACT should be obtained from the arterial line into the dialyzer, before the infusion of heparin, to reflect systemic anticoagulation effects.

Heparin-free dialysis is an alternative to heparinization for hemodialysis patients who are at a moderate-to-high risk of bleeding or who are actively bleeding.[14] This approach requires priming the hemodialysis circuit and dialyzer with heparin 3,000 units/L in normal saline to coat the extracorporeal surfaces. The heparin-containing priming fluid is allowed to drain by filling the circuit with either the patient's blood or normal saline alone at the outset of dialysis. Next, hemodialysis is set at a high blood flow rate of 300 to 400 mL/minute, if tolerated. During dialysis, the dialyzer is flushed with normal saline every 15 to 30 minutes to rinse away microclots that may have formed. The incidence of clotting with this approach is approximately 5%.

The regional administration of trisodium citrate through the arterial line is an alternative to systemic anticoagulation. It binds free calcium, which is necessary for the coagulation process. The calcium citrate complex is removed by the dialysate and, based on plasma calcium values, calcium chloride is administered on the venous side to replace the citrate-bound calcium to prevent hypocalcemia or hypercalcemia. Some of the administered citrate is returned to the patient and is metabolized to bicarbonate, leading to metabolic alkalosis in some cases. Trisodium citrate may lead to hypernatremia. Regional citrate anticoagulation is reserved for patients who are at risk for bleeding and requires additional monitoring to adjust the dual infusions.[14] In a prospective study of 1,009 consecutive high-flux dialysis procedures in 59 patients, long-term citrate anticoagulation achieved excellent anticoagulation (99.6%) with rare (0.2%) adverse effects on ionized calcium levels, electrolytes, and acid–base balance.[15]

CASE 30-1, QUESTION 4: Can low-molecular-weight heparins (LMWH) be used for hemodialysis?

Enoxaparin, dalteparin, and tinzaparin are LMWH that are commercially available but not yet approved by the US Food and Drug Administration (FDA) for hemodialysis. In a meta-analysis of 11 randomized trials, LMWH was compared with unfractionated heparin in ESRD patients undergoing either hemodialysis or hemofiltration. LMWH did not significantly affect the number of bleeding events (relative risk [RR], 0.96; 95% confidence interval [CI], 0.27–3.43) or extracorporeal circuit thrombosis (RR, 1.15; 95% CI, 0.70–1.91) compared with unfractionated heparin.[16] In a randomized, crossover study comparing the safety and efficacy of enoxaparin with standard heparin, a dose of 1.0 mg/kg body weight of enoxaparin produced less minor fibrin or clot formation in the dialyzer but more frequent minor hemorrhage between dialyses. Dosage reduction of enoxaparin to 0.7 mg/kg body weight resulted in similar efficacy and eliminated the minor hemorrhage.[17] Dalteparin administered as a single bolus dose of 60 high-flux was effective in preventing clotting of the hemodialysis circuit with no reports of bleeding.[18] Tinzaparin has also been shown to be effective as an anticoagulant during HD, using a weight-based IV dose of 75 international units/kg or a fixed IV dose of 2,500 international units just before dialysis.[19,20]

Although LMWH can be used to prevent clotting during HD, several factors need to be taken into account when considering LMWH for prevention and treatment of venous thromboembolism in HD patients. Because LMWH undergoes renal elimination, dose adjustments are necessary in patients with ESRD, accompanied by careful patient monitoring. Although LMWH inhibits factor X_a, factor XII_a, and kallikrein, measurement of antifactor X_a activity is the only available laboratory monitoring parameter for these factors; because active heparin metabolites that are not detected by the factor X_a assay can accumulate in dialysis patients, the clinical utility of this test is unclear.[21–23]

Another concern with LMWH is that patients on dialysis exhibit greater sensitivity to its effect than healthy volunteers.[23] Furthermore, LMWH administered at fixed-weight doses and without monitoring shows unpredictable anticoagulant effects in patients with stage 4 and 5 CKD. In a case series of patients on HD treated with LMWH for acute coronary syndrome, two patients who received as few as two to three doses of LMWH exhibited dialysis–access site bleeding, hematuria, and massive melena. Another subject who received 10 doses experienced hemorrhagic pericardial effusion, resulting in death. Only one patient in the series, who received a total of five doses, did not have hemorrhagic complications.[24] Based on these findings, it is recommended that unfractionated heparin, rather than LMWH, be used in patients on dialysis for prophylaxis and treatment of thromboembolic disease.[25,26]

CASE 30-1, QUESTION 5: Which agents can be used for anticoagulation during hemodialysis in patients with heparin-induced thrombocytopenia (HIT)?

HIT is reported to occur in 0% to 12% of patients on HD receiving heparin for anticoagulation. All forms of heparin, including “heparin-free” dialysis and LMWH must be stopped in patients with HIT. Another class of agents with potential use in patients requiring anticoagulation during HD is the direct thrombin inhibitors, argatroban and lepirudin. The place in therapy for these agents is in individuals who experience HIT. Argatroban is a synthetic derivative of L-arginine, which is approved by the FDA for use in patients susceptible to thrombosis who also have a history of HIT. Most dosage regimens for argatroban consist of an initial bolus dose at the start of HD followed by a continuous infusion during dialysis.[27] Because it is eliminated by non-renal routes, argatroban dosing in patients with renal failure is the same as for patients with normal kidney function.[28] However, dose adjustments are required in hepatic impairment. Murray et al.[29] evaluated three argatroban regimens in patients having high-flux hemodialysis. Anticoagulation was more consistently achieved (ACT > 140% of baseline) when a continuous infusion of 2 mcg/kg/minute with or without a bolus of 250 mcg/kg was used. The infusion was discontinued 1 hour before the end of the HD session. Approximately 20% of argatroban was removed during HD. Argatroban therapy provided adequate, safe anticoagulation throughout HD. No thrombosis, bleeding, or other serious adverse events occurred.[29]

Another antithrombin product, lepirudin, is produced through recombinant DNA technology. It is biologically similar to hirudin, which is isolated from the saliva of leeches. Unlike argatroban, lepirudin is significantly cleared by the kidneys and by most high-flux dialyzers.[30] The loading dose for intermittent hemodialysis in patients with HIT, who need anticoagulation to prevent clotting during dialysis, is 0.2 to 0.5 mg/kg (5–30 mg) with individualized dosage adjustment based on residual renal

---

function.[14,31] An activated partial thromboplastin time ratio (APTTr) measured prior to the next dialysis session targeting an APTTr < 1.5 and, where available, a lepirudan assay targeting a therapeutic range of 0.5 to 0.8 mcg/mL are used to guide dose adjustments.[14] An antidote is not available; however, fresh frozen plasma or factor VIIa concentrates can be used if major bleeding occurs. Bivalirudin is a potential alternative for anticoagulation in patients with HIT, who are at risk for major bleeding. Among the direct thrombin inhibitors, it has the shortest half-life of 25 minutes (in patients without renal dysfunction). Dosing is still being elucidated. A retrospective cohort study of 24 ICU patients undergoing intermittent hemodialysis found that an average dose of 0.07 mg/kg/hour achieved an APTT goal of 1.5 to 2.5 times baseline values,[32] while bivaluridin infused at a lower rate 1.0 to 2.5 mg/hour (0.009–0.023 mg/kg/hour) targeting an APTTr of approximately 1.5 was reported for patency of the hemodialysis circuitry.[33]

Two heparinoids, danaparoid and fondaparinux, have been evaluated for anticoagulation in hemodialysis patients with HIT; however, danaparoid was withdrawn from the United States, and fondaparinux is currently not approved for hemodialysis. A preliminary study found that fondaparinux can be used as an anticoagulant only in patients using low-flux polysulfone dialyzers.[34] An increased risk of thrombosis occurred with high-flux dialyzers attributed to increased removal of fondaparinux, resulting in inadequate anticoagulation. Further studies are necessary to define the role of this agent in patients on chronic HD.

Complications

HYPOTENSION

CASE 30-1, QUESTION 6: The dry weight for R.W. is 69.1 kg. During his most recent dialysis session, he complained of nausea and light-headedness 3 hours into the procedure. His diastolic pressure had dropped from 85 to 60 mm Hg. Ultrafiltration was discontinued, and he recovered without further event. His postdialysis weight was 69.9 kg. What are the possible etiologies for his hypotension?

In addition to solute removal, the artificial kidney must be used to maintain fluid balance in the patient without renal function. Most patients will become anuric once stabilized on HD, requiring control of ingested fluids between treatment sessions. Fluid removal during dialysis is then necessary to achieve the “dry weight,” or weight below which the patient could become symptomatic from volume depletion. Achieving the dry weight is accomplished by ultrafiltration, through adjustment of the transmembrane pressure. The dry weight for R.W. has been set at 69.1 kg. Below this weight, R.W. exhibited symptoms of orthostasis.

Intradialytic hypotension (IDH) can produce a variety of clinical signs and symptoms, including nausea and vomiting, dizziness, muscle cramps, and headache. The reported incidence of hypotension is 10% to 30%, and even higher in patients with specific risk factors, such as autonomic dysfunction associated with diabetes and cardiac disease. It primarily is caused by excessive fluid removal from the vascular compartment at a rate exceeding mobilization of fluid from the interstitial space. As a consequence, patients with an inadequate hemodynamic response to intravascular volume depletion will exhibit a decrease in blood pressure and other symptoms. An ultrafiltration rate greater than 10 mL/hour/kg was found to be associated with higher odds of IDH (odds ratio = 1.30; $p = 0.045$) and a higher risk of mortality (RR, 1.02; $p = 0.02$).[35] It may be necessary to adjust the dry weight upward if the patient is volume-depleted and symptomatic after dialysis.

Other causes of hypotension relate to rises in core body temperature. Sympathetic nervous system activity increases in response to ultrafiltration, leading to vasoconstriction of the dermal circulation and impaired heat dissipation. Increased central heat production can occur during the dialysis procedure. The increase in core body temperature can overcome peripheral vasoconstriction, resulting in hypotension. Excessive heating of dialysate can also produce vasodilation. Cooling of the dialysate to slightly below body temperature may correct this problem, although many patients are uncomfortable and do not tolerate the cooling effect. Eating during dialysis can also cause a fall in blood pressure because of vasodilation of the splanchnic vessels. While food is usually prohibited during dialysis, patients prone to IDH should avoid eating just before dialysis. Antihypertensive therapy before dialysis may exacerbate hypotensive episodes as well; in some patients, these drugs may need to be withheld until after the dialysis session has ended. Immediate treatment of the hypotensive episode can be accomplished by reclining the patient, administering a small (100 mL) bolus of normal saline into the venous blood line, and reducing the ultrafiltration rate.

Several pharmacologic agents have been proposed for the management of IDH, including ephedrine, fludrocortisone, caffeine, vasopressin, L-carnitine, sertraline, and midodrine. Perazella[36] reviewed these agents for their potential use in the treatment of IDH and concluded that only midodrine, sertraline, and L-carnitine show potential benefit in patients. Midodrine is an oral prodrug that is converted to desglymidodrine, a selective α_1-agonist. Doses of 10 to 20 mg, 30 minutes before dialysis are effective for most patients, but the presence of active myocardial ischemia is a major contraindication.[36] Sertraline is a selective serotonin reuptake inhibitor that has shown promise in IDH at daily doses of 50 to 100 mg/day. The mechanism is proposed to be improvement of autonomic function. However, neither midodrine or sertraline have shown additive effects to that of using cool dialysate.[37,38] L-Carnitine has also been tried for treatment of IDH with IV doses of 20 mg/kg at dialysis. Its mechanism of action is not known, but it may be related to improvements in vascular smooth muscle and cardiac functioning.[36] However, a meta-analysis of five studies examining the role of L-carnitine supplementation for IDH failed to confirm a benefit.[39]

An accurate assessment of R.W.'s dry weight is essential. R.W. reports gaining a few extra pounds. If weight gain is related to increased volume, then sodium restriction is needed to minimize weight gain because of fluid retention between dialysis sessions. Another consideration is a change in his lean mass. When questioned about his diet, R.W. reports an improvement in his appetite. It is important to consider "real" weight changes when assessing the dry weight and volume status. Without appropriately increasing the dry weight goal to compensate for his real weight gain, R.W. became volume depleted and hypotensive. His dry weight should be adjusted upward to the point at which he no longer is symptomatic (to approximately 70 kg).

CASE 30-1, QUESTION 7: What other hemodialysis-related complications must be watched for and how can they be treated?

MUSCLE CRAMPS

Perhaps also related to fluid shifts, muscle cramps experienced during dialysis may be induced by excessive ultrafiltration, resulting in altered perfusion of the affected tissues. Several treatments have been attempted, including reduced ultrafiltration, and infusion of hypertonic saline or glucose (in nondiabetic patients) for cramps occurring near the end of dialysis.[40] Exercise and stretching of the affected limbs may also be beneficial. Short-term daily administration of vitamin E 400 IU alone or in combination with vitamin C has been found to reduce episodes of cramping.[41,42]

Vitamin E can cause bleeding and potentiate bleeding with warfarin. Vitamin C therapy is known to produce hyperoxaluria, oxalate-containing urinary stones, and renal damage; therefore, vitamin C supplementation is limited to 60 to 100 mg daily. The long-term effects of vitamin E and vitamin C administration in hemodialysis patients are unknown.

DIALYSIS DISEQUILIBRIUM

Dialysis disequilibrium is a syndrome that has been recognized since the initiation of HD more than 30 years ago. Its etiology is related to cerebral edema, and patients new to HD are at a greater risk because of the accumulation of urea.[43] Rapid removal of urea from the extracellular space lowers plasma osmolality, thereby leading to a shift of free water into the brain. Lowering of intracellular pH, as can occur during dialysis, has also been suggested as a cause. Clinical manifestations occur during or shortly after dialysis and include central nervous system effects, such as headache, nausea, altered vision, and in some cases, seizures and coma. Treatment is aimed at prevention by initiating dialysis gradually by using shorter treatment times at lower blood flow rates in new patients. Direct therapy can be provided in the form of IV hypertonic saline or mannitol.[43]

THROMBOSIS

Dialysis access loss is most often the result of thrombosis, which is usually a consequence of venous stenosis. Prospective monitoring of access function (e.g., intra-access flow; static or dynamic venous pressures; measurement of access recirculation; and physical findings, such as swelling of the arm, clotting of the graft, prolonged bleeding after needle removal, or altered character of the pulse or thrill) is paramount to the prevention of thrombosis. Fistula patency generally is much greater than synthetic graft patency, although thrombosis and loss of function may occur in both.[6] The stenosis may be corrected by percutaneous transluminal angioplasty or, if necessary, surgical revision of the access site. Successful correction is effective as a means to prevent thrombosis. Once it occurs, thrombosis is managed by surgical or mechanical thrombectomy, or use of thrombolytic agents. Alteplase, reteplase, and tenecteplase appear to be effective for thrombolysis of the vascular access site.[44–46] Thrombolytic therapy should be avoided in those patients with an increased risk of bleeding.

For patients who have tunneled, cuffed hemodialysis catheters for hemodialysis, the success rates for clearing occlusions was greatest with reteplase at 88% ± 4%, then alteplase at 81% ± 37%, and tenecteplase at 41% ± 5% with no serious adverse bleeding events reported for thrombolytic therapy.[47] Catheter-locking regimens of heparin 3 times per week or recombinant tissue plasminogen activator instead of heparin at the midweek hemodialysis session was found to reduce the incidence of catheter malfunction and bacteremia.[48]

CASE 30-1, QUESTION 8: Do oral anticoagulants or antiplatelet agents have a role in preventing clots in R.W.'s HD access site?

Anticoagulants and antiplatelet agents have been evaluated in the prevention of graft thrombosis. A large, multicenter, randomized, placebo-controlled trial found a modest effect of extended-release dipyridamole and low-dose aspirin in reducing HD graft stenosis during the period immediately after graft placement, and improving patency duration by 6 weeks.[49] However, approximately three-fourths of patients had loss of graft patency at 1 year. Bleeding occurred at a similar rate (12%) in the treatment and placebo groups. In a cost–utility analysis, aspirin alone was found to be the most cost effective approach,[50] but no prospective studies have evaluated aspirin alone in preventing graft thrombosis. In two separate randomized, placebo-controlled trials, therapy with low-dose warfarin to achieve a target international normalized ratio of 1.4 to 1.9 or combination therapy with clopidogrel and aspirin in patients with polytetrafluoroethylene grafts showed no benefit in the prevention of thrombosis or prolongation of graft survival.[51,52] In both studies, patients receiving active treatment experienced a significantly increased risk of bleeding. A small single-center, randomized, placebo-controlled clinical trial found that fish oil reduced graft thrombosis[52]; however, this benefit was not borne out in a larger, multicenter, randomized, controlled trial.[53]

Based on these studies, oral anticoagulants or antiplatelet agents have no defined role for prophylaxis of graft thrombosis.

INFECTION

CASE 30-1, QUESTION 9: Assessment of the hemodialysis access site is performed at every treatment to identify any signs and symptoms of an access infection. Should R.W. be given prophylactic antibiotics (e.g., cefazolin with each dialysis) to avoid infection of his hemodialysis access site? Explain your rationale.

Access infections, usually involving grafts to a greater extent than a native fistula, are predominantly caused by Staphylococcus aureus or Staphylococcus epidermidis. Infections with gram-negative organisms as well as Enterococcus species occur with a lower frequency.[6] Access infections can lead to bacteremia and sepsis with or without local signs of infection.

There is no evidence that prophylactic antibiotics are of value; to the contrary, indiscriminate use of antibiotics could lead to colonization with resistant organisms. Thus, R.W. should not receive a prophylactic antibiotic. However, if evidence of infection is present, a prompt response is important. K/DOQI clinical practice guidelines for vascular access also advocate surgical incision and resection of infected grafts. Fistula infections are rare and should be treated as subacute bacterial endocarditis with 6 weeks of antibiotic therapy.[6]

CASE 30-2

QUESTION 1: D.B. a 56-year-old, 75 kg woman who undergoes high-flux hemodialysis 3 times a week develops fever, chills, and leukocytosis. What are your recommendations for empiric antibiotic therapy for suspected hemodialysis catheter-related infection?

Antibiotics that permit dosing during or after each dialysis session or antibiotics whose pharmacokinetics are unaffected by dialysis should be chosen. Treatment usually is initiated with vancomycin 20 mg/kg loading dose infused during the last 60 to 90 minutes of dialysis, and then 500 mg during the last 30 minutes of each subsequent dialysis session, depending on the type of dialysis being used.[54] High-flux dialysis results in greater removal of vancomycin than conventional dialysis. Intradialytic dosing of vancomycin is a convenient mode of drug administration in patients receiving high-flux dialysis. It avoids the need for additional intravenous access, longer stays in the hemodialysis unit, or home antibiotic administration. Cefazolin 20 mg/kg after each dialysis session can be used instead of vancomycin in dialysis units with a low prevalence of methicillin-resistant staphylococci.[54] Empiric antibiotic therapy should also include coverage for gram-negative bacilli, with antibiotic selection based on the local antibiogram. For example, gentamicin (or tobramycin) 1 mg/kg, not to exceed 100 mg infused after each dialysis session can be used for empiric gram-negative coverage with appropriate serum concentration monitoring.[54]

CASE 30-2, QUESTION 2: What are your dosing recommendations for intravenous vancomycin and gentamicin therapy for D.B., and how are the infusions prepared?

D.B. weighs 75 kg, therefore she should receive a vancomycin loading dose of 1,500 mg. Parenteral vancomycin is prepared by reconstituting 10 g of sterile vancomycin powder with 96 mL of Sterile Water for Injection for a concentration of 100 mg/mL. Fifteen mL of the vancomycin 100 mg/mL solution is further diluted in 500 mL of 5% dextrose or 0.9% sodium chloride injection, and infused during the last 90 minutes of hemodialysis. For the maintenance dose, vancomycin 500 mg IV (premixed bag) is infused during the last 30 minutes of each subsequent dialysis session. D.B. should receive gentamicin 75 mg infused over 30 minutes after dialysis. Parenteral gentamicin is prepared by diluting the 75 mg dose with 50 to 100 mL of 5% dextrose or 0.9% sodium chloride injection. Vancomycin and gentamicin doses are adjusted according to serum concentrations measured before the next hemodialysis session targeting predialysis concentrations of approximately 20 mg/mL for vancomycin and 3 mg/mL for gentamicin. Subsequent antibiotic therapy should be tailored based on culture and sensitivity results. Antibiotic therapy is continued until blood cultures are negative, no other source of infection is identified, and signs and symptoms of infection have resolved (e.g., resolution of fever and leukocystosis).

Other long-term complications associated with HD include aluminum toxicity, amyloidosis, and malnutrition.

ALUMINUM TOXICITY

Aluminum accumulation in patients undergoing HD was a significant problem before water sources were adequately treated to remove aluminum. Major complications of aluminum toxicity include dementia, aluminum bone disease, and anemia. Aluminum accumulation still occurs in patients treated with aluminum-containing phosphate binders, although not to the degree associated with water supplies. (See Chapter 28, Chronic Kidney Disease, for further discussion.)

AMYLOIDOSIS

Amyloidosis is a painful complication of ESRD caused by the deposition of β_2-microglobulin–containing amyloid in joints and soft tissues over time. Carpal tunnel syndrome, manifested as weakness and soreness in the thumb from pressure on the median nerve, is the most common symptom. Bone cysts also appear along with joint deposition of amyloid, which can lead to chronic arthralgias, joint immobility, bone fractures, and substantial disability. The incidence of amyloidosis is approximately 50% after 12 years of dialysis and nearly 100% after 20 years. β_2-microglobulin (molecular weight, 11,800 Da) is normally eliminated by filtration and tubular catabolism in the intact nephron. Renal failure leads to reduced elimination and accumulation of this substance even during dialysis. High-flux membranes are more effective than conventional membranes for the removal of β_2-microglobulin. Unfortunately, β_2-microglobulin production can exceed its elimination even by high-flux membranes. Initial treatment of carpal tunnel syndrome includes splinting of the wrists and analgesics for pain relief. Newer generations of dialysis membranes may hold some promise in reducing the development of amyloidosis.

MALNUTRITION

Chronic kidney disease produces a catabolic state in patients and, along with the multifactorial complications of ESRD, leads to malnutrition. Serum albumin concentrations less than 3.0 g/dL are associated with an increased mortality rate compared with higher values. Inadequate dietary intake and losses of amino acids by dialysis contribute to protein malnutrition, which in turn can lead to additional complications, such as impaired wound healing, susceptibility to infection, and others. (See Chapter 28, Chronic Kidney Disease, for further discussion.)

L-Carnitine

L-Carnitine supplementation has been used in patients with ESRD to relieve intradialytic symptoms. It is a metabolic cofactor that facilitates transport of long-chain fatty acids into the mitochondria for energy production. This cofactor is found in both plasma and tissue as free carnitine, the active component, or bound to fatty acids as acylcarnitine. The primary source of carnitine is dietary intake, primarily from red meat and dairy products. Carnitine is a small water-soluble molecule that is freely dialyzed, thus its levels are reduced in hemodialysis. The potential benefits of correcting this relative carnitine deficiency have been primarily studied in patients having chronic HD. Although some have suggested that carnitine supplementation benefits muscle cramps and hypotension during dialysis (as well as minimizing fatigue, skeletal muscle weakness, cardiomyopathy, and anemia resistant to large doses of erythropoietic therapy), no evidence supports its routine use in patients undergoing chronic HD.[55]

PERITONEAL DIALYSIS

Peritoneal dialysis is performed using several different modalities, including the most common, CAPD. Development of specialized devices to facilitate the exchange process and improve patient convenience has led to processes referred to as APD, including continuous cycling peritoneal dialysis (CCPD) and nocturnal intermittent dialysis (NIPD). CAPD is the most common method for chronic PD, but the APD methods have grown in popularity, especially among the pediatric population. Although lower rates of peritonitis are observed in APD compared with CAPD,[56] other outcomes measures, such as need for transition to HD and mortality, are similar between the two modalities.[57]

Principles and Transport Processes

Continuous ambulatory peritoneal dialysis is performed by the instillation of 2 to 3 L of sterile dialysate solution into the peritoneal cavity through a surgically placed resident catheter. The solution dwells within the cavity for 4 to 8 hours, and then it is drained and replaced with a fresh solution. This process of fill, dwell, and drain is performed 3 to 4 times during the day, with an overnight dwell by the patient in his or her normal home or work environment (Fig. 30-2). Conceptually, the process is similar to HD in that uremic toxins are removed by diffusion down a concentration gradient across a membrane into the dialysate solution. In this case, the peritoneal membrane covering the abdominal contents serves as an endogenous dialysis membrane, and the vasculature embedded in the peritoneum serves as the blood supply to equilibrate with the dialysate. A primary difference is that because the dialysate solution is resident, the result is a very slow dialysate flow rate of approximately 7 mL/minute when 10 L of fluid is drained per day. Solute loss occurs by diffusion for small molecules, and through convection for larger, middle molecules.

BLOOD AND DIALYSATE FLOW

Hemodialysis provides constant perfusion of fresh dialysate, thereby maintaining a large concentration gradient across the dialysis membrane throughout the dialysis treatment. Unlike hemodialysis, during a typical dwell period for CAPD, urea and other substances increase in the dialysate relative to unbound plasma concentrations. For a daytime dwell period of 4 hours, urea achieves nearly equal concentrations with plasma; therefore, the rate of elimination can become very small. Instillation of fresh dialysate solution will reestablish the diffusion gradient, leading to an increased rate of urea removal. For a patient making four exchanges of 2 L each per day, assuming the urea dialysate concentration equals the plasma concentration, and 2 L are removed by ultrafiltration, the urea clearance would be approximately 7 mL/minute. This is substantially lower than urea clearances achieved with HD; therefore, CAPD must be performed continually (daily) throughout the week to achieve adequate urea removal. Clearance depends on blood flow; dialysate flow; and peritoneal membrane characteristics such as size, permeability, and thickness. Dialysate flow, the only easily adjusted variable to alter clearance, has been used effectively in acute PD to achieve relatively high clearances with 30- to 60-minute dwell periods in a cycling system. CCPD uses this concept of shorter dwell periods during the sleeping hours with automatic fill, dwell, and drain periods, leaving a high-dextrose dialysate in the peritoneal cavity throughout the day until the next cycling session. NIPD is similar, with nightly exchanges, but the peritoneum is left unfilled, or dry, during the daytime. As a result, urea clearance is lower with NIPD, but it may be suitable for many patients, and preferable to the volume load in the peritoneal cavity throughout the day with CCPD.[58] Electrolyte concentrations in the dialysate solution are near physiologic concentrations to prevent substantial shifts in serum electrolyte levels (Table 30-1). A potential advantage of PD compared with HD is the continuous dialysis of larger, middle molecules that have been implicated as a possible source of toxic effects. These molecules are cleared through convection and follow water as it is removed through ultrafiltration. Clearance of these molecules depends less on flow and more on duration of dialysis. The continuous process of PD, although associated with low clearance values, provides for a more physiologic condition in patients, rather than the intermittent treatment provided with HD.

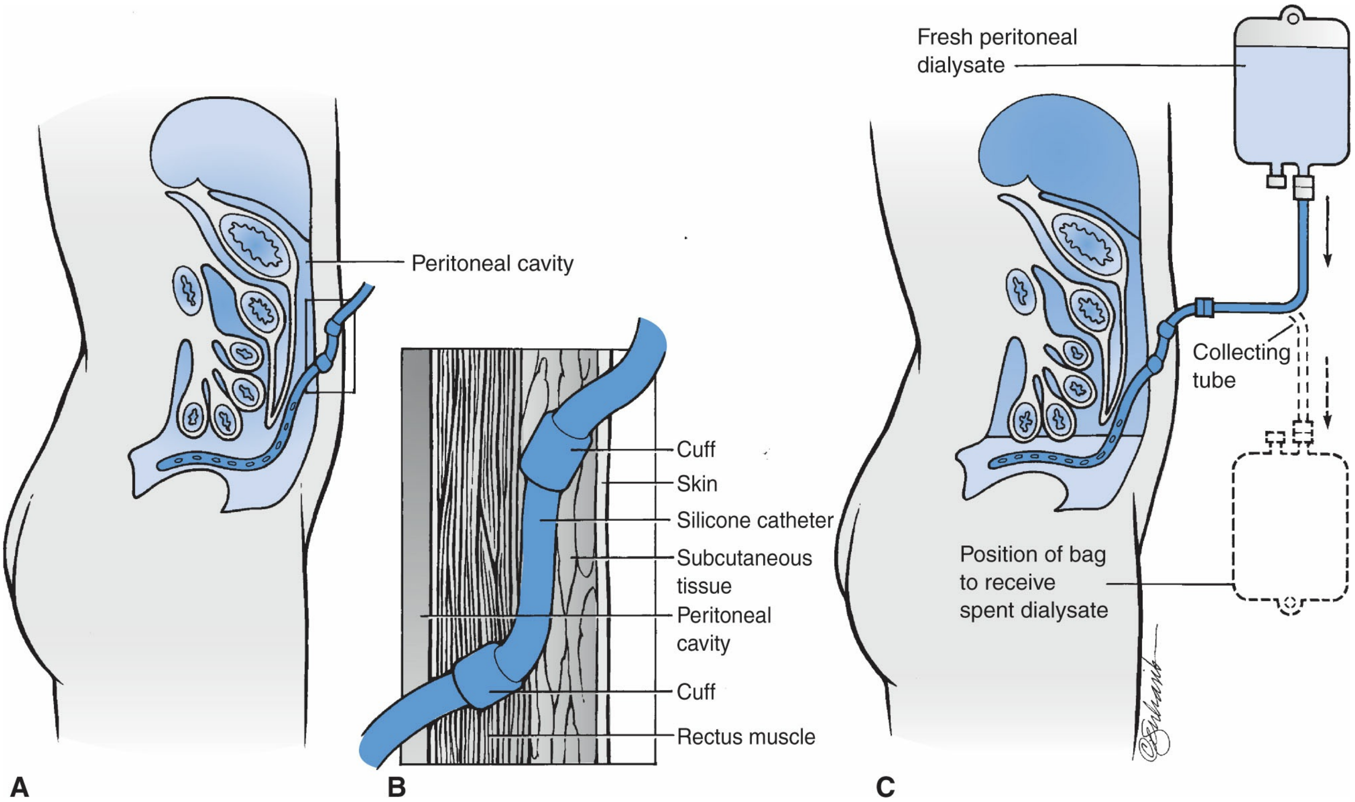

Figure 30-2 Continuous ambulatory peritoneal dialysis. **(A)** The peritoneal catheter is implanted through the abdominal wall. **(B)** Dacron cuffs and a subcutaneous tunnel provide protection against bacterial infection. **(C)** Dialysate flows by gravity through the peritoneal catheter into the peritoneal cavity. After a prescribed period of time, the fluid is drained by gravity and discarded. New solution is then infused into the peritoneal cavity until the next drainage period. Dialysis thus continues on a 24-hour-a-day basis during which the patient is free to move around and engage in his or her usual activities. Adapted with permission from Smeltzer SC, Bare BG. Textbook of Medical-Surgical Nursing. 9th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2000.

FLUID REMOVAL

Fluid is removed by ultrafiltration through adjustment of the transmembrane pressure during HD. Because this pressure is not easily adjusted in PD, fluid is removed by altering the osmotic pressure within the dialysate. This is accomplished by the addition of dextrose (glucose monohydrate) to the dialysate in varying concentrations, depending on the degree of fluid removal necessary in the patient. Concentrations of dextrose in commercially available solutions include 1.5%, 2.5%, and 4.25%, with net fluid losses during a 4-hour dwell period of 200 mL and 400 mL for the 1.5% and 2.5% solutions, respectively, and approximately 700 mL for the 4.25% solution after an overnight dwell.[59] As the dwell time persists, the dextrose is absorbed and is diluted by the movement of fluid from the vascular space, so that most ultrafiltration occurs early during the dwell period.

Bicarbonate is not compatible with the calcium and magnesium in the dialysate and can lead to precipitation; therefore, lactate is used in the dialysate. Acid–base balance is achieved through the absorption of lactate from the dialysate, which subsequently is metabolized to bicarbonate in vivo.

Access

Delivery of dialysate into the peritoneal cavity is accomplished through an indwelling catheter inserted through the abdominal wall. The most common design is the Tenckhoff catheter, made of silicone rubber or polyurethane; it consists of a tube, straight or curled, with many holes in the distal end for fluid inflow and outflow. The catheter also has a single or double cuff, which serves to anchor it to the internal and external attachment sites by promoting fibrous tissue growth; this also serves as a barrier to bacterial migration. Several modifications to the original catheter have appeared on the market, mostly in an attempt to overcome problems related to outflow of dialysate. Maintaining an unobstructed outlet port is essential for successful PD.

Delivery of dialysate through the catheter is accomplished using Y sets and double-bag systems. The Y transfer set uses three limbs of tubing, with fresh dialysate attached to the upper arm of the Y, an empty bag to the lower arm, and the stem connected to the catheter. Clamping the inflow arm and opening the stem and outflow arm allow dialysate to drain from the peritoneum into the empty bag. Reversing the clamps then permits infusion of the fresh dialysate solution after a small rinse of the line is performed with the fresh solution. Clamping of the catheter allows removal of the Y transfer set and bags from the patient. The double-bag system uses pre-attached bags to both limbs and the patient and makes only a single connection to the catheter. Use of the Y transfer set has reduced episodes of peritonitis from approximately one for every 9 to 12 patient-months to one for every 24 to 36 patient-months.[60] PD performed with the cycler involves only two disconnections of the system, compared with four for CAPD.

Dialysis Prescription

CASE 30-3

QUESTION 1: M.J., a 27-year-old woman, has a 14-year history of type 1 diabetes mellitus. She is 5 feet, 5 inches tall and weighs 65 kg. One complication of her diabetes is ESRD necessitating dialysis. She has been undergoing CAPD for 1 year and, until now, has done well without any complications. Her dialysis prescription consists of three exchanges with 1.5% dextrose during the day and a fourth, overnight exchange with 4.25% dextrose. She has a double-cuff Tenckhoff catheter and uses a Y transfer set for her exchanges. Her blood pressure is controlled and she shows no evidence of edema. She has no residual renal function. What is the purpose of the addition of 1.5% dextrose to M.J.'s dialysate? Why would the concentration of dextrose be increased to as high as 4.25% in some situations?

The initial CAPD prescription for most patients consists of three exchanges during the day with 1.5% dextrose and a fourth, overnight, exchange with 4.25% dextrose. This would be expected to achieve fluid removal of approximately 1,300 mL, based on 200 mL from each daytime exchange and 700 mL overnight. Based on the assessment of the patient's fluid status, it may be necessary to increase or decrease the dialysate prescription to achieve fluid balance. Fluid retention is solved by increasing the dextrose content of the daytime exchanges, beginning with 2.5% in place of one of the 1.5% solutions. This is expected to result in an additional removal of 200 mL, and therapy can be further adjusted as necessary. For patients with excessive fluid removal, it may be possible to decrease the number of exchanges per day as long as adequate solute removal is present. If four exchanges are needed, the fluid intake can be liberalized to maintain adequate hydration.

Dextrose is the dextrorotatory form of glucose. Glucose is a small molecule that rapidly diffuses across the peritoneal membrane. As glucose is absorbed, the osmotic gradient of the dwell progressively dissipates, reducing ultrafiltration. Toward the end of the long dwell, more dialysate fluid may be absorbed than ultrafiltered, resulting in a negative net ultrafiltration volume where the drained volume is less than the infused volume. A negative net ultrafiltration volume is undesirable. Greater ultrafiltration and fluid management are predictors of survival.[61]

An alternative to dextrose as the osmotic agent in the dialysate solution is icodextrin, a starch-derived, water-soluble, non-dextrose polymer that is approximately 40% absorbed and subsequently metabolized to maltose oligosaccharides. Icodextrin is approved for use in the United States in patients having CAPD or APD during the long-dwell period. Unlike glucose, icodextrin does not readily diffuse across the peritoneal membrane, but it is slowly removed from the peritoneal cavity via convective uptake into the peritoneal lymphatics.[62] It is superior to dextrose solutions for ultrafiltration.[63] Icodextrin has been shown to have less glucose absorption, carbohydrate exposure, fat accumulation, and weight gain than glucose-containing PD fluids.[64]

A number of factors need to be considered when icodextrin is used. Insulin requirements may decrease when icodextrin is substituted for dextrose solutions during the long dwell. On the other hand, a more worrisome concern is that icodextrin can cause false elevations in glucose concentrations with certain glucose-monitoring devices unable to distinguish glucose from maltose.[65] In this situation, insulin and other medications used to manage hyperglycemia may be increased unnecessarily, resulting in iatrogenic hypoglycemia. A pharmacovigilance report identified three cases of iatrogenic hypoglycemia in patients undergoing peritoneal dialysis with icodextrin, with two of these patients in the ICU for severe hypoglycemia.[66] Other undesirable effects of icodextrin include skin rash, mild hyponatremia, sterile peritonitis, and false reductions of serum amylase concentrations which can complicate the diagnosis of pancreatits.[65]

PERITONITIS

CASE 30-3, QUESTION 2: M.J. now presents to the dialysis clinic with complaints of abdominal tenderness and cloudy effluent. Examination of the dialysate reveals a white blood cell (WBC) count of 330 cells/μL with

62% neutrophils. Gram stain is positive for gram-positive cocci. Her diabetes has been controlled by the addition of 10 units of regular insulin to each daytime bag and 15 units to the overnight bag. While awaiting cultures, dual therapy with cefazolin and ceftazidime is ordered. Is this treatment coverage appropriate? Provide the dosages and administration for M.J.'s infection.

The most significant complication among patients undergoing PD is peritonitis. The patient usually presents with abdominal pain, nausea and vomiting, and fever with or without a cloudy effluent. The effluent should be inspected and sent to the laboratory for cell count with differential, Gram stain, and culture, with antibiotic therapy initiated in the interim. Bacterial peritonitis generally is accompanied by an elevated dialysate WBC count greater than 100/μL with greater than 50% neutrophils. Specific consensus recommendations of the International Society for Peritoneal Dialysis Ad Hoc Advisory Committee on Peritoneal Dialysis-Related Infections are located at http://www.ispd.org.[67]

Empiric antibiotics must cover both gram-positive and gram-negative organisms.[67] The increasing prevalence of vancomycin-resistant organisms has resulted in a shift in empiric therapy away from vancomycin, toward first-generation cephalosporins (cefazolin or cephalothin). Without a Gram stain, therapy should be initiated with a combination of cefazolin or cephalothin (to cover gram-positive organisms) and ceftazidime (to cover gram-negative organisms), coadministered by the intraperitoneal route (IP) in the same dialysate solution at a dose of 15 mg/kg (rounded to the nearest 500 mg) for both drugs, once daily.[67] M.J. weighs 65 kg, therefore a 1 g dose cefazolin and ceftazidime IP is appropriate. Both antibiotics are available as 1 g vials. To prepare the doses for IP administration, each sterile antibiotic powder is reconstituted with 3 to 10 mL of Sterile Water for Injection and shaken well. The contents are withdrawn into separate syringes and injected into the peritoneal dialysis bag. Separate syringes must be used to add the antibiotics to dialysis solutions. An aminoglycoside can be used in place of ceftazidime. While aminoglycosides were not found to adversely affect residual renal function,[68] high systemic

absorption and prolonged half-life of gentamicin was found in patients with peritonitis, which can lead to drug accumulation.[69] Short-term use appears to be safe and effective, but there is a potential risk of toxicity, such as oto- and/or vestibular toxicity, with prolonged therapy. Gentamicin, tobramycin, or netilmicin are given at doses of 0.6 mg/kg/bag, once daily, and for amikacin, 2 mg/kg/bag once daily. Antibiotics should be allowed to dwell for at least 6 hours, and the minimum duration of therapy is 2 weeks.[67] M.J. should receive the antibiotics in the overnight bag, since it has the longest dwell time. Subsequent antibiotic therapy should be based on culture and sensitivity results, incorporating specific dosage regimens based on the treatment guidelines.

This is M.J.'s first episode of peritonitis. The most likely pathogen, a Staphylococcus species, is consistent with the positive Gram stain. Her treatment should consist of monotherapy with cefazolin (or cephalothin) 15 mg/kg IP daily as ordered. Ceftazadime should be discontinued. Vancomycin should not be used for empiric therapy. Instead, it should be reserved for methicillin-resistant S. aureus infections or methicillin-resistant S. epidermidis if M.J. does not respond to empiric therapy.

CASE 30-3, QUESTION 3: A new order is written to add heparin to M.J.'s dialysate fluid. What is the reason for this? She is also receiving insulin intraperitoneally. Is this appropriate or should she be switched to subcutaneous insulin?

In addition to antibiotics, heparin 500 units/L should be added to each exchange to prevent fibrin clots from forming, obstructing outflow from the peritoneal cavity, and occluding the catheter.[67] M.J.'s blood glucose should be monitored, because infection causes insulin resistance and peritonitis will increase glucose and insulin absorption. Inability to control the blood glucose concentration may require temporary discontinuation of the intraperitoneal (IP) insulin and administration by another route. Also see Case 30-2, Question 7, for other considerations regarding insulin dosing.

CASE 30-3, QUESTION 4: If M.J. was receiving APD instead of CAPD, would the treatment of her infection be different?

Cycler machines automatically cycle dialysate into and out of the peritoneal cavity in APD. Patients having CCPD will generally need three to five exchanges, each lasting approximately 2 hours, using a cycler while the patient sleeps. During the daytime hours, the patient maintains a reservoir of dialysate in the peritoneal cavity, resulting in a long dwell. The cycler process repeats at night. Six to eight exchanges are performed every night for patients having NIPD. The peritoneum is left dry, and patients do not continue dialysis during the day. Nightly dwell times are generally 1 to 2 hours for each exchange, resulting in a higher clearance for small molecules because of the increased dialysate flow rate.[58]

For patients having APD, the choice of first-line antibiotics is the same as for CAPD because the likely organisms are similar. Drug dosage regimens, however, can differ because patients having CCPD or NIPD undergo PD only during the nighttime hours, and those having NIPD do not have residual peritoneal fluid during the day. The rapid exchanges in APD may lead to inadequate time to achieve therapeutic drug concentrations. The dose of cefazolin in APD is 20 mg/kg (rounded to the nearest 500 mg) every day, in the long day dwell.[67] M.J. should receive cefazolin 1,500 mg IP in the long day dwell. A concern is that patients given a single dose of a cephalosporin during the long day dwell may have IP levels at night that are below the MIC of most organisms allowing biofilm-associated organisms to survive, resulting in relapsing peritonitis.[67] A safer approach would be to add the cephalosporin to each exchange in APD. Because of the lack of clinical trials with other antibiotics in patients having APD, extrapolation from the CAPD literature may be necessary. A review addresses the current knowledge and issues surrounding the pharmacokinetics of antibiotics in patients with peritonitis undergoing APD.[70]

EXIT-SITE INFECTION: PROPHYLAXIS

CASE 30-3, QUESTION 5: Catheter exit-site infections are a significant risk factor for developing peritonitis. What information should be provided to educate M.J. in daily catheter care? Recommend an appropriate antimicrobial cream for M.J. to administer around the catheter exit site.

Prevention of catheter exit-site infections (and thus peritonitis) is the primary goal of exit-site care. Several preventative measures are important: adequate catheter placement, dedicated postoperative catheter care, and routine daily care of the exit site. Dressing changes of a newly placed catheter are done by a dialysis nurse using sterile technique until the exit site is well healed, which can take up to 2 weeks. Once the exit site is well healed, M.J. can be educated and trained to do routine exit-site care, including thorough hand cleansing before touching the exit site by rubbing both hands for at least 15 seconds using antiseptics that contain at least 70% alcohol or antibacterial soap.[71] The exit site is then washed daily with antibacterial soap, although use of an antiseptic (e.g., povidone iodine or chlorhexidine) is a reasonable option as long as concentrations are non-cytotoxic.[72] Hydrogen peroxide should be avoided as a routine antiseptic because it causes drying. After daily cleansing, M.J. can be instructed to apply antimicrobial creams (e.g., mupirocin, gentamicin) around the catheter exit site using a cotton swab. Mupirocin ointment, not the cream, can cause structural damage to polyurethane catheters and should be avoided in patients with these catheters.[72]

Catheter exit-site infections are most often caused by S. aureus and Pseudomonas species.[67] In a randomized, double-blind trial, gentamicin sulfate 0.1% cream was found to be as effective as mupirocin 2% cream in preventing S. aureus infections.[73] Gentamicin cream was also highly effective in reducing Pseudomonas aeruginosa and other gram-negative catheter infections, whereas mupirocin cream was not. A longer time to first catheter infection and a reduction in peritonitis, particularly gram-negative organisms, was also seen with gentamicin use. For these reasons, daily gentamicin cream at the exit site is considered to be the prophylaxis of choice in patients having PD and would be the preferred treatment for M.J. Finally, the catheter should be immobilized with a small gauze dressing and tape to prevent pulling and trauma to the exit site, which may lead to infection.

EXIT-SITE INFECTION: TREATMENT

CASE 30-3, QUESTION 6: If M.J. were to exhibit an exit-site infection despite appropriate catheter care, could oral therapy be used or is intraperitoneal therapy required?

Empiric therapy for exit-site infections may be started immediately and should always cover S. aureus. Oral antibiotic therapy has been shown to be as effective as IP therapy with the exception of methicillin-resistant S. aureus infections.[67] Local erythema alone can be treated with topical agents, whereas purulent drainage indicates more significant infection and the need for systemic antibiotics. Gram-positive organisms are treated with first-generation oral cephalosporins, or with oral penicillinase-resistant penicillins. Rifampin may be added at 600 mg/day orally (in single or split dose) for slowly resolving infections. It should not be used as monotherapy, or in areas where tuberculosis is endemic. Rifampin is an inducer of drug-metabolizing enzymes and concurrent medications should be evaluated for potential drug interactions.

Oral quinolone antibiotics are recommended as first-line agents in the treatment of P. aeruginosa exit-site infections. Monotherapy is not recommended because resistance develops rapidly, and P. aeruginosa infections are difficult to treat often requiring prolonged therapy with two antibiotics. If the infection is slow to resolve or if in cases of a recurrence, a second antipseudomonal drug can be added (e.g., ceftazidime IP). Gram-negative organisms can be treated with ciprofloxacin 500 mg orally twice daily.[74] Scheduling of the quinolone dose is important, so that coadministration with foods or other drug therapies that may chelate the quinolone in the gut is avoided. Potentially chelating agents include calcium products, iron, multivitamins, antacids, zinc, sucralfate, and dairy products. Antibiotic therapy should be continued for a minimum of 2 weeks until the exit site appears entirely normal.

WEIGHT GAIN

CASE 30-3, QUESTION 7: M.J. is noted to have gained weight since starting peritoneal dialysis. Besides fluid retention, what other possible cause is there for the weight gain? How might this affect her insulin requirements?

Dextrose is present in dialysate solutions primarily to serve as an osmotic agent for the removal of fluid during each exchange. Higher concentrations are expected to result in greater fluid removal. Approximately 500 to 1,000 kcal/day are absorbed as glucose from PD solutions, which can lead to weight gain in patients. Some patients may require modification of oral caloric intake to avoid excessive weight gain. Insulin requirements generally are increased in patients with diabetes as a result of the additional calories and, when administered IP, usually are 2 to 3 times the normal subcutaneous dose because of their reduced bioavailability of 20% to 50% by this route. Also see Case 30-3, Question 3, for other considerations regarding insulin dosing.

Dosing of Drugs in Renal Failure

David J. Quan

CORE PRINCIPLES		CHAPTER CASES
1	The pharmacokinetics and pharmacodynamics of many drugs are altered in patients with impaired renal function (e.g., declining glomerular filtration rate) or who are on renal replacement therapy.	**Case 31-1 (Questions 1, 2), Case 31-2 (Question 1), Case 31-3 (Questions 1, 3), Case 31-4 (Questions 1, 2), Case 31-5 (Questions 1, 4), Case 31-8 (Questions 1–3)**
2	Clinicians should be aware of drugs that require dosage adjustment in the setting of renal dysfunction to avoid adverse drug events and poor patient outcomes.	**Case 31-1 (Questions 1, 2), Case 31-3 (Questions 1, 3), Case 31-4 (Question 1, 2), Case 31-5 (Questions 1, 4)**
3	Dosages of drugs that are cleared by the kidneys should be adjusted according to the patient's renal function (e.g., creatinine clearance). The initial dose can be determined using the manufacturer's prescribing information, published guidelines, or published literature.	**Case 31-1 (Questions 1, 4), Case 31-3 (Question 3), Case 31-4 (Question 1), Case 31-5 (Questions 1, 4, 5)**
4	Many drugs have a narrow therapeutic window (range of drug concentrations that will achieve the desired effect), for which there may be lack of efficacy with subtherapeutic levels and adverse events associated with elevated levels. Therapeutic drug concentration monitoring should be performed to achieve the desired target concentration.	**Case 31-1 (Questions 2, 3), Case 31-5 (Question 2), Case 31-7 (Question 1), Case 31-8 (Question 3)**
5	Renal replacement therapy (e.g., hemodialysis, continuous venovenous hemofiltration) can have a significant influence on the extracorporeal removal of drug. Clinicians should be aware of the method of renal replacement therapy and its impact on drug dosing.	**Case 31-1 (Questions 5–8), Case 31-2 (Questions 1, 2), Case 31-3 (Questions 1, 4), Case 31-5 (Questions 3, 4), Case 31-6 (Question 1)**
6	Biotransformation of drugs may be altered in patients with renal failure. Active or toxic metabolites may accumulate in patients with renal failure, leading to adverse effects. Excipients such as diluents can also accumulate in the setting of renal failure, resulting in toxicity.	**Case 31-3 (Question 2), Case 31-8 (Questions 1, 2)**

BASIC PRINCIPLES

The kidneys play an important role in the disposition of many drugs. It is important to design specific pharmacotherapeutic regimens for patients with renal impairment. Without careful dosing and therapeutic drug monitoring for select medications in these patients, accumulation of drugs or toxic metabolites can occur, resulting in serious adverse effects. Many patients are treated with multiple medications, which may require even greater attention to dosage adjustment.

In addition to altered drug elimination, numerous other factors associated with kidney disease predispose patients to potential drug toxicity by altering the pharmacokinetic disposition and the pharmacodynamic effects of drugs. For example, the physiologic changes associated with uremia can change drug absorption, protein binding, distribution, or elimination. These physiologic effects can alter drug concentrations in the plasma or blood, and at the targeted tissue site of activity, thereby affecting drug efficacy and toxicity.

Less is known about the effect of renal disease on drug pharmacodynamics, i.e., the pharmacologic or toxicologic effects

produced relative to the drug concentration. Patients with renal disease can be more sensitive to some drugs, and experience an increased frequency of adverse drug reactions.

Effect of Renal Failure on Drug Disposition

BIOAVAILABILITY

Although several factors can potentially affect drug absorption in patients with kidney disease, limited data are available describing altered bioavailability. For example, drug absorption could be impaired in uremia by nausea, vomiting, diarrhea, gastritis, and edema of the gastrointestinal (GI) tract, the latter condition being a complication of nephrotic syndrome. Gastric and intestinal motility, as well as gastric emptying time, can be altered by the neuropathy associated with uremia. Uremia also can increase gastric ammonia, leading to an increased gastric pH, which may affect the bioavailability of drugs that require an acidic environment for absorption such as ferrous sulfate.[1] Similarly, calcium-containing antacids used by patients with renal failure for GI symptoms and hyperphosphatemia neutralize hydrochloric acid in the stomach and increase gastric pH. Patients with end-stage renal disease (ESRD) often take oral phosphate binders, such as sevelamer and lanthanum carbonate, which can impair the absorption of other medications.[2,3]

The bioavailability of orally administered drugs also depends on the extent to which the drug is eliminated by first-pass (presystemic) metabolism. The first-pass hepatic metabolism of oral propranolol was found to be reduced in patients with renal disease, leading to increased bioavailability.[4] Subsequent studies, however, attributed the observed increased concentrations of propranolol in renal failure to a significant increase in the blood to plasma ratio.[5] Intestinal P-glycoprotein activity may be decreased as well.[6] Other drugs exhibiting increased bioavailability in renal disease include cloxacillin, propoxyphene, dihydrocodeine, encainide, and zidovudine (AZT). For example, the area under the concentration–time curve of dihydrocodeine is increased by 70% in those patients with impaired renal function.[7]

PROTEIN BINDING AND VOLUME OF DISTRIBUTION

The extent to which a drug exerts its pharmacologic effects is related to the amount of free or unbound drug available for distribution to target tissues. Patients with renal failure often have alterations in plasma protein binding, which can increase the amount of unbound drug.[8] Clinically, this is most important for highly protein-bound acidic drugs (>80%), whereas the binding of basic drugs is usually unchanged or possibly decreased in renal disease. Decreased protein binding of affected drugs results in increases in the free fraction of drug, an increase in the apparent volume of distribution (Vd), and higher plasma clearance (Cl) for drugs with a low-extraction ratio. However, the simultaneous increase in both the Vd and clearance results in little or no change in the elimination half-life ($t_{1/2}$) of these drugs. Alternatively, the Vd of high-extraction ratio drugs can increase without a concomitant change in clearance. In this situation, the $t_{1/2}$ would increase, based on the following relationships, where Kd is the elimination rate constant of the drug:

$$\mathrm{Kd} = \mathrm{Cl}/\mathrm{Vd} \qquad \text{(Eq. 31-1)}$$

$$t_{1/2} = 0.693 \times \mathrm{Vd}/\mathrm{Cl} \qquad \text{(Eq. 31-2)}$$

In patients with renal failure, the accumulation of uremic toxins may also alter protein binding. When the free fraction of drugs that are highly protein bound changes, the interpretation of the total drug concentration must also be considered. That is, with an increase in the free fraction, the total drug concentration necessary to exert the desired pharmacologic effect is lower than that needed under normal conditions.

Table 31-1

Plasma Protein Binding (%) of Acidic Drugs in Renal Failure

Drug	Normal	Renal Failure
Cefazolin	85	69
Cefoxitin	73	25
Clofibrate	97	91

Diazoxide	94	84
Furosemide	96	94
Pentobarbital	66	59
Phenytoin	88–93	74–84
Salicylate	87–97	74–84
Sulfamethoxazole	66	42
Valproic acid	92	77
Warfarin	99	98

Hypoalbuminemia is a common complication of renal failure. Because acidic rather than basic drugs are bound to albumin, their protein binding tends to be altered in patients with renal failure (Table 31-1).[9] Patients with uremia accumulate acidic by-products that may inhibit binding or displace acidic drugs from albumin binding sites. This is supported by the observed improvement in protein binding after removal of uremic by-products by hemodialysis. Finally, the structural conformation of albumin is altered in renal disease, which may reduce the number or affinity of binding sites for drugs. Studies have demonstrated differences in the amino acid composition of albumin between healthy people and patients with uremia.[10] The anticonvulsant, phenytoin, is a classic example of a drug whose protein binding is altered in renal disease.[11] This is discussed in more detail later in this chapter.

Renal disease can change the Vd of various drugs. The Vd or “apparent volume of distribution” is the “volume” or size of a compartment necessary to account for the total amount of drug in the body if it were present throughout the body at the same concentration as that found in plasma. A decrease in the plasma protein binding of highly protein-bound drugs, such as phenytoin, leads to an increase in the apparent Vd.

Drugs that are not highly protein bound (e.g., gentamicin, isoniazid) have little change in their Vd in renal disease. Digoxin is a unique exception in that its Vd is decreased in renal disease. This is attributed to a decrease in myocardial tissue uptake of digoxin, leading to a decrease in the myocardial or tissue to serum concentration ratio.[12]

ELIMINATION

The extent to which renal disease affects the elimination of a drug depends on the amount of drug normally excreted unchanged in the urine and the degree of renal impairment. As kidney disease progresses, the kidney’s ability to excrete uremic toxins diminishes. Consequently, the ability to eliminate certain drugs that are renally excreted also decreases. If the dose of these drugs is not modified for the patient’s degree of renal dysfunction, these drugs will accumulate, potentially leading to an increase in the pharmacologic effect and toxicity.

The kidney eliminates drugs primarily by filtration or active secretion. Characteristics of a drug that determine its ability to be filtered include its affinity for protein binding and its molecular weight (MW). Drugs with low protein binding or those that are

---

displaced from proteins in the setting of renal disease are filtered more readily. Molecules with a high MW (>20,000 Da) are not readily filtered because of their large size. The reasons for how renal disease selectively alters the process of glomerular filtration or tubular secretion of specific drugs are not well understood. The elimination of drugs by the kidneys in patients with renal disease usually can be estimated by measuring the ability of the kidney to eliminate substances such as creatinine (i.e., creatinine clearance [CrCl]) (see Chapter 29, Acute Kidney Injury).

Organic anion transporters (OATs) are predominantly found in the basolateral membrane of the renal tubules. OATs facilitate the uptake of small organic anions into renal tubular cells. Decreased OAT activity as a result of acute kidney injury can decrease the renal secretion of various drugs such as methotrexate, nonsteroidal antiinflammatory drugs, and acetylsalicylic acid.[13]

Renal disease can also have an important impact on the elimination of drugs that are primarily metabolized by the liver.[14] Metabolic processes, such as hydroxylation and glucuronidation, often produce inactive, more polar compounds that can be eliminated by the kidney. The metabolites of some drugs (e.g., meperidine, morphine, procainamide) are pharmacologically active or toxic. In patients with renal disease, these metabolites may accumulate, leading to an increase in pharmacologic activity and adverse effects.[15,16] For example, the central nervous system (CNS) toxicity observed in renal disease has been attributed to accumulation of the morphine metabolite, morphine-6-glucuronide. Therefore, careful dosing modifications or avoidance of these drugs is warranted in patients with renal impairment. Metabolic enzymes have been found within renal tissue, and may play a role in the metabolism of some drugs.[17,18] For example, the nonrenal clearance of drugs (e.g., acyclovir) decreases in patients with renal impairment, and is believed to be caused by a decrease in "renal" metabolism.[19]

Excipients used to formulate medications should also be considered. For example, the pharmacokinetics of itraconazole and voriconazole are not significantly altered in the setting of renal dysfunction. However, the parenteral formulations of itraconazole, posaconazole, and voriconazole contain the solubilizing agent, β-cyclodextrin, which is normally rapidly eliminated by glomerular filtration but can accumulate in patients with renal impairment, causing GI disturbances.[20]

Drug Removal by Dialysis

The effect of dialysis on the removal of a specific drug must be considered when using medications in patients undergoing dialysis. Patients may need supplemental doses of a medication after a dialysis session or alteration in their dosage to maintain therapeutic drug concentrations. Dialysis also can be initiated to hasten drug removal from the body in some cases of drug overdose.

When using dialysis to manage a drug overdose, patients may respond clinically to factors unrelated to dialysis of the drug. For example, declining plasma concentrations may be caused by concurrent drug elimination by hepatic metabolism or renal excretion, which is independent of the dialysis procedure itself. Furthermore, clinical improvement may result from removal of active metabolites by dialysis rather than the parent compound.

The primary literature should be used to determine whether any information is available about the ability of dialysis to remove the drug. The application of data from the literature to a specific clinical situation often is difficult, however, and information pertaining to the dialysis of a specific drug may be limited.

When applying information from the primary literature to a specific patient, the specifics of the dialyzer (e.g., type of machine, membrane surface area, pore size, and blood and dialysis flow rates) must be considered (see Chapter 30, Renal Dialysis). Furthermore, patient-specific information (e.g., time of drug ingestion, liver and renal function) from case reports in the literature also should be evaluated appropriately. The method used to calculate dialysis clearance also should be considered. In addition, clinical investigators often use predialysis and postdialysis serum drug concentrations for estimating drug dialyzability without considering the contributing effects of drug metabolism and excretion on drug elimination.

DRUG-SPECIFIC PROPERTIES

The physical and chemical characteristics of drugs can be used to predict the effectiveness of dialysis on drug removal.[21–23] Low MW compounds are more readily dialyzed by conventional hemodialysis procedures because they can pass with greater ease across the dialysis membrane. Using cuprophane dialysis membranes, compounds with an MW of 500 or less are more likely to be significantly dialyzed than compounds with a high MW (e.g., vancomycin, MW approximately 1,400). Newer high-flux dialyzers using polysulfone membranes more effectively remove large chemical compounds (see High-Flux Hemodialysis Section, and Chapter 30, Renal Dialysis). In addition, water-soluble drugs (e.g., aminoglycosides, lithium) are removed more readily by dialysis than are lipid-soluble compounds (e.g., diazepam) or those that partition into red blood cells (e.g., tacrolimus).

Pharmacokinetic characteristics (e.g., Vd, protein binding) also can affect drug dialyzability. A drug with a large Vd that distributes widely into the peripheral tissues resides minimally in the plasma and, therefore, is not substantially removed by dialysis. This is particularly true for highly lipid-soluble drugs such as digoxin (Vd = 300–500 L) and amiodarone (Vd = 60 L/kg). In addition, drugs that are highly protein bound, such as warfarin (99%) and ceftriaxone (83%–96%), are not significantly removed by dialysis because the large protein–drug complex is unable to pass through the dialysis membrane.

Because clearance values are additive, the hepatic and other nonrenal plasma clearance of a drug should be considered in relation to the dialysis clearance. Only when dialysis clearance contributes a substantially additive effect to the patient's own clearance is drug elimination enhanced. For example, AZT has a large nonrenal plasma clearance in patients with severe renal disease (approximately 1,200 mL/minute). Therefore, despite a hemodialysis clearance of 63 mL/minute, the contribution of dialysis to total AZT removal is negligible.

HIGH-FLUX HEMODIALYSIS

High-flux hemodialysis uses higher blood and dialysate flow rates compared with conventional methods. The enhanced efficiency of high-flux dialysis and the larger pore size of the polysulfone membranes allow for small- and mid-MW compounds (e.g., vancomycin) to be partially removed. Drugs such as gentamicin and foscarnet, which are removed by conventional dialysis, are also efficiently removed by high-flux hemodialysis.[24,25] In many cases, the net amount of drug removed during a high-flux dialysis session is greater than the amount removed during conventional dialysis because of the use of higher blood flow rates. The principal difference is the greater efficiency and the ability to clear drugs of larger MW compared with conventional dialysis.

CONTINUOUS AMBULATORY PERITONEAL DIALYSIS

Continuous ambulatory peritoneal dialysis (CAPD) uses the patient's peritoneum as the dialysis membrane. Patients maintained with CAPD undergo infusion of a dialysate solution via a catheter inserted into the peritoneal cavity; the solution is allowed to dwell in the cavity for several hours. The accumulated fluid

---

and uremic by-products diffuse from the blood into the dialysate solution, which is exchanged every 4 to 8 hours (see Chapter 30, Renal Dialysis).

Some drugs, such as antibiotics, can be administered intraperitoneally (IP) in patients on CAPD by directly adding them to the dialysate solution. This is particularly useful for patients with peritonitis who require high intraperitoneal concentrations of antimicrobial agents to treat this infection. After intraperitoneal administration of drugs, such as the aminoglycosides, plasma and intraperitoneal drug concentrations will eventually reach equilibrium. Despite systemic absorption of these drugs from the peritoneal fluid, peritoneal dialysis (PD) usually is inefficient at removing drugs from the plasma.[26] Because CAPD contributes little to the overall elimination of most drugs, dosage modifications are not always necessary in patients having this procedure.

Continuous venovenous hemofiltration (CVVH) is a form of continuous renal replacement therapy (CRRT) used in the critically ill patient with renal failure. CRRT is typically reserved for patients who are unable to tolerate hemodialysis because of hemodynamic instability. As with hemodialysis, this procedure removes fluid, electrolytes, and low- and mid-MW molecules from the blood. Using a hollow fiber that is made of a semipermeable membrane, water and solutes are filtered by hydrostatic pressure. A countercurrent dialysate can be added to the circuit to improve solute removal (continuous venovenous hemodialysis with filtration).

Limited data are available on the effect of CVVH on the removal of drugs. Drugs that have a high sieving coefficient (permeability of a drug through a semipermeable membrane), such as the aminoglycosides, ceftazidime, vancomycin, and procainamide, are readily removed by CVVH.[27–29] Data concerning the removal of drugs by hemodialysis cannot be extrapolated to CVVH because of differences in the membranes used, blood flow rates, ultrafiltration rate, dialysate flow rate, and the continuous nature of the procedure compared with intermittent hemodialysis. CVVH clearance can be estimated to determine the appropriate dosage regimen based on the pharmacologic characteristics of a specific drug (see Case 31-1, Question 8).

HEMOPERFUSION

Hemoperfusion is another method of drug removal that may be used to facilitate the elimination of a drug in the setting of an overdose.[30,31] During the hemoperfusion procedure, blood is passed through a column of adsorbent material (e.g., activated charcoal or resin) to bind toxins and drugs. Hemoperfusion can be particularly useful for removing large MW compounds or highly protein-bound drugs that are not removed efficiently by hemodialysis. Large compounds and drug–protein complexes are adsorbed onto the high-surface-area resin as blood passes through the adsorbent column. Hemoperfusion can also be used to remove lipid-soluble drugs not easily removed by hemodialysis. Lipid-soluble drugs often have a large Vd. Removal of drugs by hemoperfusion is of limited value because a significant amount of these lipophilic compounds resides in peripheral tissues.

Pharmacodynamics and Renal Disease

Few studies have investigated the pharmacodynamics of drugs in patients with renal disease. Clinical observations report that patients with renal disease are more sensitive to various drugs. For example, morphine has been associated with increased neurologic depression in patients with renal failure.[32,33] The ability of morphine to potentiate the CNS-depressant effects of uremia may result from an alteration in the permeability of the blood–brain barrier that results in higher CNS levels of morphine and morphine-6-glucuronide.

Another example of altered drug response in uremia is that of nifedipine, which at similar unbound plasma concentrations has an increased antihypertensive effect in patients with renal disease.[34] The mean maximal effect change in diastolic blood pressure values in the control group and in patients with severe renal failure were 12% and 29%, respectively. Therefore, the dose of nifedipine may need to be adjusted in patients with renal disease because of changes in drug effects rather than pharmacokinetic alterations.

The pharmacokinetics of warfarin is not significantly altered in renal failure. However, patients with renal failure who are prescribed warfarin have a higher incidence of hemorrhagic complications, likely because of platelet dysfunction from uremia, and drug–drug interactions from concomitant medications.[35,36]

PHARMACOKINETICS AND PHARMACODYNAMICS OF SPECIFIC DRUGS IN RENAL FAILURE

Ceftazidime

DOSAGE MODIFICATION: FACTORS TO CONSIDER

CASE 31-1

QUESTION 1: G.G., a 31-year-old, 70-kg woman with a 3-year history of systemic lupus erythematosus, presents to the emergency department (ED) with a 5-day history of fatigue, weakness, and nausea as well, as worsening of her facial rash and a fever of 40°C. Her systemic lupus erythematosus had been moderately controlled until this acute flare. Her admission laboratory workup now reveals the following pertinent values:

Potassium (K), 6.0 mEq/L
Sodium (Na), 142 mEq/L
Serum creatinine (SCr), 3.4 mg/dL
Blood urea nitrogen (BUN), 38 mg/dL

Complete blood count reveals a hematocrit of 32% and a hemoglobin of 9.2 g/dL. The platelet count is 50,000/µL, and her erythrocyte sedimentation rate is 35 mm/hour. Physical examination is significant for a blood pressure of 136/92 mm Hg and 2+ pedal edema. Prednisone is started at a dose of 1.5 mg/kg/day.

During her hospital course, G.G.'s condition worsens and signs of sepsis develop. Pseudomonas aeruginosa is cultured from her urine. Therapy with ceftazidime is initiated at a dose of 2 g every 8 hours, a dose commonly used for patients with normal renal function. Considering that G.G.'s renal function has remained stable and that she has an estimated CrCl of 27 mL/minute, what factors should be considered before modifying her dose? What would be an appropriate dose of ceftazidime for G.G.?

Before modifying the dose of any drug, its route of elimination should be established. As a general rule, the degree to which renal impairment affects elimination depends on the percentage of unchanged drug that is excreted by the kidney. Thus, the elimination of most drugs that are primarily cleared by the kidneys will be decreased in the setting of renal impairment. For many drugs dependent on the kidney for elimination, relationships between some measurement of renal function (e.g., CrCl) and some parameter of drug elimination (e.g., plasma clearance or half-life) have been established to help clinicians determine the appropriate dosing modifications in patients with renal disease.

In contrast, the clearance of drugs that are eliminated primarily by nonrenal mechanisms (e.g., hepatic metabolism) is not altered significantly in patients with renal disease. However, some drugs have water-soluble metabolites that have either pharmacologic activity or potential toxicity and that may accumulate with renal dysfunction, warranting dosage adjustment or avoidance of the drug entirely (e.g., meperidine; see Case 31-8, Question 1).

Enzymes with metabolic capacity have also been found within renal tissue, which can result in the kidneys playing a limited role in the metabolism of certain drugs (see Case 31-3, Question 2). The clinical importance of this elimination pathway is unclear.

Another important factor to consider is the “therapeutic window” for a given drug, i.e., the range of drug concentrations thought to be most effective. Drug concentrations below this range are usually subtherapeutic, whereas concentrations above this range can lead to a greater incidence of adverse effects. For drugs with a wide therapeutic window, the difference between toxic and therapeutic concentrations is large. Although many drugs that are cleared primarily by the kidney may require dosing modifications in patients with renal dysfunction, aggressive dose reduction may not be necessary for drugs with a large therapeutic window, particularly if the adverse effects of the drug (e.g., fluconazole) are relatively mild. This is in contrast to drugs (e.g., aminoglycosides, vancomycin, or foscarnet) that are eliminated primarily by the kidney and have narrow therapeutic windows. For these drugs, the toxic plasma concentrations are very close to the therapeutic drug concentrations, with little room for dosing error.

Ceftazidime is a cephalosporin that has excellent activity against most strains of Pseudomonas species. As with most cephalosporins, ceftazidime primarily is cleared by the kidneys, with little nonrenal or hepatic elimination. The correlation between the clearance of ceftazidime and CrCl in mL/minute is represented by the following equation[37]:

$$\mathrm{Cl}_{\mathrm{ceftaz}}(\mathrm{mL/minute}) = (0.95)(\mathrm{CrCl}) + 6.59 \qquad \text{(Eq. 31-3)}$$

Using Equation 31-3, the clearance of ceftazidime in G.G. is estimated to be 32 mL/minute compared with an average normal clearance of approximately 100 mL/minute. Because her drug clearance is approximately one-third of normal, she would require about one-third of the normal daily dose (i.e., 2 g every 24 hours). As with other cephalosporins, ceftazidime has a large therapeutic window.[38] Failure to reduce the dose from a normal dose of 2 g every 8 hours, although likely safe, might lead to accumulation of ceftazidime, predisposing G.G. to seizures and other adverse effects associated with toxic β-lactam antibiotic plasma levels.[39,40] This is in contrast to the aminoglycosides, which must be dosed based on specific pharmacokinetic calculations. Therefore, more generalized or empirical dosage modifications can be made with ceftazidime.

Aminoglycosides

CASE 31-1, QUESTION 2: G.G.'s medical team decides that the addition of an aminoglycoside antibiotic is necessary to treat her infection. Considering that her renal function has remained stable, how should gentamicin be dosed in G.G.? Is it best to alter the dose or the dosing interval for this drug?

ALTERATION OF DOSE VERSUS DOSING INTERVAL

The aminoglycosides (e.g., tobramycin, gentamicin, amikacin) are effective in the treatment of serious systemic infections caused by gram-negative organisms such as Pseudomonas species. Unlike the cephalosporins and penicillins, however, the aminoglycosides have a relatively narrow therapeutic window. Using pharmacokinetic principles, a dose regimen can be designed to produce specific peak and trough serum concentrations. Peak serum concentrations (Cp_{peak}) (e.g., gentamicin or tobramycin 5–8 mg/L) correlate best with therapeutic efficacy, whereas toxicity tends to correlate with elevated trough levels (Cp_{trough}), which reflects prolonged exposure to high drug concentrations. To minimize the risk of toxicity, trough levels of less than 2 mg/L should be maintained. In patients with normal renal function, these target serum aminoglycoside concentrations are usually obtained after standard doses (e.g., 1.5 mg/kg) administered every 8 hours. Peak and trough levels are typically measured once steady state is achieved, which is typically within 24 hours.[41–44]

Many clinicians now use once-daily dosing of the aminoglycosides (e.g., 5 mg/kg every 24 hours) for patients with normal renal function in an attempt to minimize aminoglycoside accumulation and nephrotoxicity. The rationale for this regimen is based on the aminoglycosides' concentration-dependent killing and postantibiotic effect. This approach is not recommended for patients with advanced renal impairment, however. When once-daily dosing is used, peak concentrations are less helpful; however, trough concentrations should be monitored with a target of being below the limit of analytic detection (<1 mg/L). The discussion regarding aminoglycoside dosing in renal impairment that follows is based on the traditional every 8 hours dosing regimen.

Aminoglycosides are almost completely eliminated by the kidneys; thus, the clearance of these drugs essentially is equal to the glomerular filtration rate (GFR). The pharmacokinetic properties of gentamicin and tobramycin are similar. A close correlation also exists between CrCl (a surrogate for GFR) and gentamicin total body clearance. As renal function deteriorates, aminoglycoside doses must be modified to achieve the desired peak and trough plasma concentrations. Failure to appropriately adjust the dosage of aminoglycosides in renal insufficiency can lead to high drug plasma levels that can result in ototoxicity and nephrotoxicity.

In many cases, the aminoglycoside dose can be modified by extending the dosing interval rather than simply reducing the dose. This permits maintenance of adequate peak plasma concentrations to ensure efficacy, while allowing for sufficient elimination between doses to produce trough levels less than 2 mg/L. The advantages and disadvantages of adjusting the dosing interval versus reducing the dose are summarized in Table 31-2.

Figure 31-1 illustrates the effect of increasing the dosing interval in a patient such as G.G. with renal function that is 30% of normal. Although this is the preferred method for adjusting the dose of aminoglycosides, for many other drugs requiring dose adjustments in renal disease, simple dosage reduction is sufficient. Commonly used drug references such as Facts and Comparisons can be used for dosing guidelines for drugs used in patients with renal failure.[45]

DETERMINATION OF APPROPRIATE DOSE

A number of methods have been developed to determine the appropriate aminoglycoside dose for patients.[46] One method is Bayesian forecasting, in which pharmacokinetic data obtained in the individual patient are integrated with population parameters. Initially, a dose is used that is based on population parameter values adjusted for characteristics such as increased SCr. Drug concentrations for the individual patient are measured at specific times (e.g., peak and trough measurements), and these are compared with the expected values from the population data. Individualized pharmacokinetic parameter estimates are subsequently derived using Bayes’ theorem to calculate a more patient-specific dosing regimen.[47]

Because of the wide interpatient variability in aminoglycoside pharmacokinetic parameters and the narrow therapeutic index for these drugs, doses should be adjusted based on pharmacokinetic principles (e.g., Bayesian calculations or methods described later in this chapter) and plasma concentrations that are specific for this patient.

Table 31-2

Advantages and Disadvantages of General Approaches to Dosing Adjustments in Renal Disease

Method	Advantages	Disadvantages
Variable Frequency		
Use the same dose but ↑ the dosing interval	Same Cp_{ave}, Cp_{max},	Levels may remain subtherapeutic for prolonged periods in patients requiring

	Cp_{min} Normal dose	dosing intervals >24 hours
Variable Dose With Fixed Cp_{ave}		
↓ Dose to maintain a target Cp_{ave}; keep the dosing interval the same	Same Cp_{ave} Normal dosing interval	↓ Peak levels, which may be subtherapeutic; ↑ trough levels, which may ↑ potential for toxicity

Cp_{ave}, average plasma concentration; Cp_{max}, maximum plasma concentration; Cp_{min}, minimum plasma concentration.

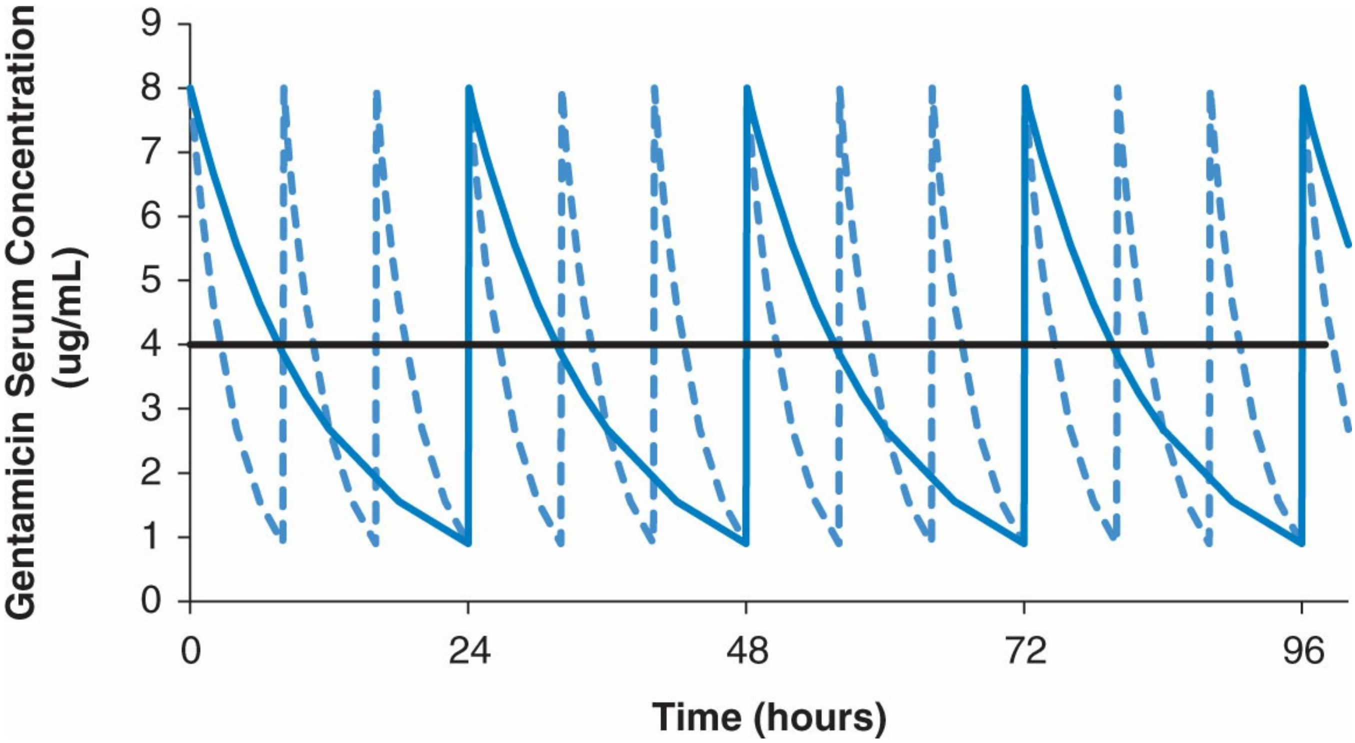

Figure 31-1 Serum concentration versus time profile for a patient with normal renal function (dotted line), and for patient G.G. (Case 31-1) whose estimated creatinine clearance is 27 mL/minute (solid lines).

Patient-Specific Methods

Sawchuk et al. developed a method to derive patient-specific estimates of Vd and clearance based on the patient's size and estimated CrCl.[43] These parameters can be used to calculate a specific dose for G.G. that will produce the desired gentamicin peak and trough concentrations. If steady-state serum concentrations of gentamicin are known, they can be used to calculate even more specific parameters. To initiate gentamicin therapy, pharmacokinetic parameters should first be estimated from population values.

The clearance of gentamicin (Cl_{gent}) can be calculated based on G.G.'s CrCl. Using the Cockcroft–Gault equation,[48] the CrCl can be estimated as follows:

$$\text{CrCl (males)} = \frac{(140 - \text{age})(\text{IBW})}{(\text{SCr})(72)} \qquad \text{(Eq. 31-4)}$$

$$\text{CrCl (females)} = \frac{(140 - \text{age})(\text{IBW})}{(\text{SCr})(72)}(0.85) \qquad \text{(Eq. 31-5)}$$

where IBW is ideal body weight in kilograms, age is measured in years, and SCr is serum creatinine in mg/dL.

With a SCr of 3.4 mg/dL, an ideal body weight of 70 kg, and an age of 31 years, G.G.'s estimated CrCl, is 27 mL/minute.

For practical purposes, Cl_{gent} is usually considered equivalent to CrCl. Therefore, Cl_{gent} also is approximately 27 mL/minute or 1.6 L/hour. The Vd of gentamicin (Vd_{gent}) is approximately 0.25 L/kg in patients with normal or impaired renal function.[43,48,49]

The Vd_{gent} will be different in obese patients or those who have fluid overload. Although G.G. does have some fluid retention, this is minimal and should not affect her Vd_{gent} significantly. Therefore, the Vd_{gent} for G.G. is as follows:

$$\begin{aligned} Vd_{gent} &= (0.25\ \text{L/kg})(\text{body weight}) \\ &= (0.25\ \text{L/kg})(70\ \text{kg}) \qquad \text{(Eq. 31-6)} \\ &= 17.5\ \text{L} \end{aligned}$$

The loading dose of gentamicin (LD_{gent}) can be determined using the following equation:

$$LD_{gent} = (Vd_{gent})(\text{desired } Cp_{peak}) \qquad \text{(Eq. 31-7)}$$

For treatment of infections caused by Pseudomonas species, a peak level of approximately 6 to 8 mg/L is desired:

$$\begin{aligned} LD_{gent} &= (17.5\ \text{L})(7\ \text{mg/L}) \\ &= 122.5\ \text{mg or round off to 120 mg} \end{aligned} \qquad \text{(Eq. 31-8)}$$

Using Cl_{gent} and Vd_{gent}, the elimination rate constant (Kd) and half-life for gentamicin can be estimated as follows:

$$\mathrm{Kd} = \frac{\mathrm{Cl}_{\mathrm{gent}}}{\mathrm{Vd}_{\mathrm{gent}}} = \frac{1.6\ \mathrm{L/hour}}{17.5\ \mathrm{L}} = 0.091\ \mathrm{hour}^{-1} \qquad \text{(Eq. 31-9)}$$

$$t_{1/2} = \frac{0.693}{\mathrm{Kd}} = \frac{0.693}{0.091\ \mathrm{hour}^{-1}} = 7.6\ \mathrm{hours} \qquad \text{(Eq. 31-10)}$$

For the aminoglycosides, the dosing interval (τ) is determined by doubling the half-life because by the end of two half-lives, 75% of the drug will have been eliminated. This will usually lead to a desired trough level of less than 2 mg/L. Therefore, gentamicin should be administered at least every 16 hours. For convenience, an interval of 24 hours can be used, which also will achieve the desired trough concentration.

Gentamicin is usually infused over 30 minutes. To determine the peak gentamicin concentration, serum samples are drawn 30 minutes after the infusion has been completed. Because the estimated elimination half-life of gentamicin in G.G. (7.6 hours) is much longer than the infusion time (0.5 hours), the intravenous (IV) bolus model can be used to calculate an appropriate maintenance dose.

To achieve the peak concentration of 7 mg/L, the following equation can be used:

$$\begin{aligned}\text{Dose} &= \frac{(\text{Cp}_{\text{peak}})(1 - e^{-\text{Kd}\tau})(\text{Vd}_{\text{gent}})}{(e^{-\text{Kd}t_{\text{sample}}})}\\ &= \frac{(7\ \text{mg/L})(1 - e^{-(0.091\ \text{hour}^{-1})(24\ \text{hour})})(17.5\ \text{L})}{(e^{-(0.091\ \text{hour}^{-1})(1\ \text{hour})})}\\ &= 119.2\ \text{mg}\\ &= \text{or round off to } 120\ \text{mg}\end{aligned} \qquad \text{(Eq. 31-11)}$$

where t_{sample} usually equals 1 hour (30 minutes after a 30-minute infusion).

The expected trough level in G.G. can now be estimated by the following equation:

$$\begin{aligned}\text{Cp}_{\text{trough}} &= (\text{Cp}_{\text{peak}})(e^{-\text{Kd}\tau_{\text{sample}}})\\ &= (7\ \text{mg/L})(e^{-(0.091\ \text{hour}^{-1})(24\ \text{hours})})\\ &= 0.8\ \text{mg/L}\end{aligned} \qquad \text{(Eq. 31-12)}$$

Although not the case for G.G., patients with normal renal function may eliminate a significant amount of gentamicin during the 30-minute infusion. In these patients, the intermittent infusion model should be used to account for this loss of drug, where t_{in} is the duration of the infusion:

$$\text{Dose} = \frac{(\text{Cl}_{\text{gent}})(\text{Cp}_{\text{peak}})(1 - e^{-\text{Kd}\tau})(t_{\text{in}})}{(1 - e^{-\text{Kd}\tau_{\text{in}}})(e^{-\text{Kd}\tau})} \qquad \text{(Eq. 31-13)}$$

REVISED PARAMETERS

CASE 31-1, QUESTION 3: After 72 hours of gentamicin therapy, G.G.'s peak and trough levels are 7.6 and 2.6 mg/L, respectively. Her physician attributes this to a gradual decline in renal function. (Her most recent SCr is 4.8 mg/dL.) How would you revise G.G.'s dosing regimen based on these levels?

A gentamicin trough level of more than 2 mg/L suggests that G.G.'s dosing interval is too short. Although her peak concentration is within the normal range of 5 to 8 mg/L, her trough concentration indicates that she is at a potentially toxic level. Her pharmacokinetic parameters can be revised based on these values, and a new Kd can be estimated from the following equation:

$$\mathrm{Kd} = \frac{\ln\left(\dfrac{\mathrm{CP}_1}{\mathrm{CP}_2}\right)}{\Delta t} = \frac{\ln\left(\dfrac{7.6\ \mathrm{mg/L}}{2.6\ \mathrm{mg/L}}\right)}{23\ \mathrm{hours}} = 0.047\ \mathrm{hour}^{-1} \qquad \text{(Eq. 31-14)}$$

Because little change in G.G.'s $\mathrm{Vd}_{\mathrm{gent}}$ is expected, a new $\mathrm{Cl}_{\mathrm{gent}}$ ($\mathrm{Cl}_{\mathrm{revised}}$) can be estimated from her revised elimination constant (if necessary, a revised $\mathrm{Vd}_{\mathrm{gent}}$ could be calculated, keeping $\mathrm{Cl}_{\mathrm{gent}}$ constant, although the clearance is more likely to change than the volume of distribution):

$$\begin{aligned}\mathrm{Cl}_{\mathrm{revised}} &= (\mathrm{Vd}_{\mathrm{gent}})(\mathrm{Kd}) \\ &= (17.5\ \mathrm{L})(0.047\ \mathrm{hour}^{-1}) \\ &= 0.82\ \mathrm{L/hour}\end{aligned} \qquad \text{(Eq. 31-15)}$$

These revised values for Kd and Cl can now be used to calculate a revised maintenance dose to maintain the $\mathrm{Cp}_{\mathrm{trough}}$ at less than 2 mg/L using Equation 31-11:

$$\begin{aligned}\mathrm{Dose} &= \frac{(7\ \mathrm{mg/L})(1 - e^{-(0.047\ \mathrm{hour}^{-1})(48\ \mathrm{hours})})(17.5\ \mathrm{L})}{e^{-(0.047\ \mathrm{hour}^{-1})(1\ \mathrm{hour})}} \\ &= 115\ \mathrm{mg} \\ \mathrm{Cp}_{\mathrm{trough}} &= (7\ \mathrm{mg/L})(e^{-(0.047\ \mathrm{hour}^{-1})(48\ \mathrm{hours})}) \\ &= 0.73\ \mathrm{mg/L}\end{aligned} \qquad \text{(Eq. 31-16)}$$

The revised dose is now 115 mg (or ~110 mg) every 48 hours.

CASE 31-1, QUESTION 4: What are some limitations in calculating G.G.'s CrCl based on her SCr? Can this estimate safely be used to predict gentamicin clearance?

See Chapter 28, Chronic Kidney Disease, for information about equations used to calculate CrCl and estimate GFR. For patients with stable renal function, CrCl can be estimated from SCr using the Cockcroft–Gault equation (see Eqs. 31-4 and 31-5). In a patient such as G.G., however, whose renal function continues to decline during the hospital course, estimation of renal function based on her increasing SCr becomes more difficult. Because her SCr does not reflect a steady-state level, the previous equations can no longer be used to accurately estimate her renal function. Because G.G.'s SCr has increased rapidly from 3.4 to 4.8 mg/dL during the past few days, her CrCl is probably much lower than that estimated using the Cockcroft–Gault method. A rising SCr may represent a decline in renal function manifesting as an accumulation of creatinine.

Although prediction equations such as the Modification of Diet in Renal Disease (MDRD) equations are a good measure of GFR,[50] they were developed in patients with chronic kidney disease, therefore limiting its use in healthy patients. In addition, the MDRD equation has not been validated for the dosing of most drugs in the setting of renal dysfunction.[51,52] There can be significant differences in drug dosing regimens when the MDRD and Cockcroft–Gault methods are used to estimate renal function.[53,54] In 1998, the FDA recommended using the Cockcroft–Gault equation to estimate kidney function when designing pharmacokinetic clinical trials and drug dosing regimens. The Cockcroft–Gault equation has been the standard method to estimate renal function to determine if drug dosage adjustments are necessary. In 2010, the FDA released a draft guidance that included both the Cockcroft–Gault and MDRD equations to determine renal function. It also should be noted that the units for the Cockcroft–Gault equation for CrCl is mL/minute, while the units for the MDRD equation for eGFR is mL/minute/1.73m^2. The manufacturer's prescribing information and available literature should be evaluated to determine the appropriate dosage regimen based on the patient's renal function.

Effect of Hemodialysis

CONVENTIONAL DIALYSIS

Gentamicin

CASE 31-1, QUESTION 5: G.G.'s renal function continues to deteriorate to the extent that she requires hemodialysis. What additional alterations in her gentamicin dosing regimen are necessary when she is having dialysis?

Gentamicin has a MW of about 500 and a relatively low Vd (averaging 0.25 L/kg), and is about 10% bound to proteins, all favoring effective removal by conventional hemodialysis.[44] For a given patient, the observed dialysis clearance of gentamicin using conventional methods also depends on factors such as the physical properties of the dialysis filter, the blood and dialysate

---

flow rates, and the length of dialysis. Studies indicate that dialysis clearance of gentamicin averages 45 mL/minute compared with an average plasma clearance of 5 mL/minute in patients with ESRD.[55,56] Therefore, G.G.'s gentamicin dose must be adjusted to compensate for the amount of drug that will be removed by dialysis. Because drug removal represents a combination of drug elimination by the body and dialysis, the following equation can be used:

$$\mathrm{Cl}_{\mathrm{total}} = \mathrm{Cl}_{\mathrm{dial}} + \mathrm{Cl} \qquad \text{(Eq. 31-17)}$$

where $\mathrm{Cl}_{\mathrm{total}}$ is the total clearance of the drug during dialysis, $\mathrm{Cl}_{\mathrm{dial}}$ is the clearance by dialysis, and Cl is plasma clearance. If dialysis clearance is high relative to plasma clearance, drug removal will be enhanced by the dialysis procedure. The total clearance of gentamicin in a patient with severe renal dysfunction during dialysis is 50 mL/minute (45 mL/minute + 5 mL/minute) or 10 times the clearance while off dialysis. Plasma clearance and dialysis clearance are related to the elimination half-life by the following equation:

$$t_{1/2} = \frac{(0.693)(\mathrm{Vd})}{\mathrm{Cl}_{\mathrm{dial}} + \mathrm{Cl}} \qquad \text{(Eq. 31-18)}$$

Thus, assuming a constant Vd of 17.5 L (i.e., 0.25 L/kg × 70 kg), the elimination half-life on dialysis is approximately 4 hours compared with 40 hours off dialysis. In addition, the extent (fraction) of drug removal (FD) during a timed dialysis run can be predicted from the following equation:

$$\mathrm{FD} = 1 - e^{-(\mathrm{Cl} + \mathrm{Cl}_{\mathrm{dial}})(t/\mathrm{Vd})} \qquad \text{(Eq. 31-19)}$$

where t is the duration of dialysis. Therefore, the fraction of gentamicin removed (FD) during a 4-hour conventional dialysis procedure is approximately 50%. If specific data are not available for dialysis and plasma clearance, the following equation will predict fraction removed using the elimination half-life data alone obtained during dialysis:

$$\mathrm{FD} = 1 - e^{-(0.693/t_{1/2\mathrm{on}})(t)} \qquad \text{(Eq. 31-20)}$$

The estimated value of 50% removal is consistent with literature values indicating that 50% to 70% of a dose of gentamicin is removed during a 4-hour dialysis procedure. A limitation of this equation, however, is that it does not consider the redistribution of drug from the tissues back into the plasma after the dialysis procedure.

It generally is difficult to calculate an appropriate maintenance dose for patients having hemodialysis that will maintain peak and trough concentrations similar to patients with normal renal function, in part because of the large variability found in aminoglycoside pharmacokinetic parameters.[56,57] Sustained plasma concentrations greater than 2 mg/L can increase the risk of toxicity; however, dosing gentamicin to achieve trough concentrations of less than 2 mg/L may lead to prolonged periods of subtherapeutic peak concentrations because one would have to use smaller doses with lower peak concentrations to allow the troughs to decrease before the next dose. Another practical consideration is that unless one expects the patient to recover renal function in the future, renal toxicity of the drug is less of a concern. As a compromise in patients receiving hemodialysis, gentamicin doses are given to achieve a predialysis trough concentration of approximately 3 mg/L. This can generally be achieved with a loading dose of 2 mg/kg, followed by a maintenance dose of 1 mg/kg after each dialysis session.

Ceftazidime

CASE 31-1, QUESTION 6: Why does the dose of ceftazidime in G.G. have to be adjusted because of her hemodialysis when this drug has such a large therapeutic window?

Because only 21% of ceftazidime is protein bound and its Vd is 0.2 L/kg, it should be readily removed by hemodialysis. The mean dialysis clearance of ceftazidime is 55 mL/minute, with 55% of the drug removed during 4 hours of conventional hemodialysis.[58] A supplemental dose of ceftazidime should be given to G.G. after each hemodialysis session to maintain a therapeutic concentration. Half of the daily ceftazidime dose should be administered after each dialysis session.

HIGH-FLUX HEMODIALYSIS

CASE 31-1, QUESTION 7: G.G.'s physician is considering changing her from a conventional dialysis system to a high-flux system that uses high-efficiency polysulfone membranes. How does the dialyzability of gentamicin and ceftazidime differ with high-flux hemodialysis compared with conventional hemodialysis?

High-flux hemodialysis is more effective than conventional dialysis at removing certain pharmacologic agents (see Chapter 30, Renal Dialysis) because the membranes are more efficient and the blood flow through the dialyzer is increased. Although limited data are available, a greater fraction of drugs, such as aminoglycosides, ceftazidime, and vancomycin, are removed by high-flux versus conventional hemodialysis.[59,60] Approximately 50% to 70% of gentamicin is removed during a 2.5-hour, high-flux dialysis session.[24] The clearance of ceftazidime by high-flux dialysis is 75 to 240 mL/minute compared with 55 mL/minute for conventional hemodialysis.[59] Thus, further dosage adjustments for gentamicin and ceftazidime may be necessary if G.G. is converted from conventional hemodialysis to high-flux hemodialysis.

CONTINUOUS VENOVENOUS HEMOFILTRATION

CASE 31-1, QUESTION 8: What changes would be necessary in G.G.'s gentamicin dosing if she were to start a CRRT such as CVVH?

Because of the continuous nature of CVVH, the extent of drug eliminated by CRRTs will differ from intermittent modes such as hemodialysis. The clearance of a drug in a patient receiving CVVH can be described in a fashion similar to Equation 31-17, where Cl_{dial} is replaced with Cl_{cvvh}.

$$Cl_{total} = Cl + Cl_{cvvh} \quad \text{(Eq. 31-21)}$$

In G.G., the $Cl_{revised}$ from Equation 31-15 can be used for the plasma clearance (Cl). The clearance by CVVH can be described by the following equation:

$$Cl_{cvvh} = Fu \times UFR \quad \text{(Eq. 31-22)}$$

where Fu is the fraction of drug unbound and UFR is the ultrafiltration rate. Gentamicin exhibits low plasma protein binding (Fu = 0.95). Typical ultrafiltration rates for CVVH are approximately 1 L/hour, but can vary.

$$\begin{aligned} Cl_{cvvh} &= Fu \times UFR \\ &= 0.95 \times 1\ L/hour \\ &= 0.95\ L/hour \end{aligned} \quad \text{(Eq. 31-23)}$$

$$\begin{aligned} Cl_{total} &= Cl_{revised} + Cl_{cvvh} \\ &= 0.82\ L/hour + 0.95\ L/hour \\ &= 1.77\ L/hour \\ &= 29.5\ mL/minute \end{aligned} \quad \text{(Eq. 31-24)}$$

Because the clearance of gentamicin approximates that of CrCl, G.G.'s total clearance is approximately one-third the normal clearance of 100 mL/minute. Therefore, the gentamicin dose should be approximately one-third of the normal dose. G.G. should be given 1.5 mg/kg/day or 100 mg of gentamicin as a single daily dose (normal dose is approximately 5 mg/kg/day). Gentamicin trough concentrations should be monitored, and her dose adjusted to maintain a trough concentration of less than 2 mg/L.

CONTINUOUS AMBULATORY PERITONEAL DIALYSIS

CASE 31-2

QUESTION 1: J.J., a 24-year-old man with ESRD, is maintained with CAPD. He presents to the ED with a fever of 38.2°C and complains of severe abdominal pain. He also reports that his peritoneal dialysate has become cloudy in the past few days. All these symptoms are consistent with peritonitis, a frequent complication of CAPD. His culture results reveal Escherichia coli, sensitive to gentamicin. How should gentamicin be dosed in this patient?

Management of dialysis-related peritonitis can vary from one institution to another. Antibiotics often are administered IP with or without systemic antibiotic therapy. For less severe cases, IP administration is often considered sufficient. With IP administration, the goal is to deliver a concentration of drug similar to the desired plasma concentration for the treatment of systemic infections. Therefore, 8 mg of gentamicin into each liter of dialysate (or 16 mg into a 2-L bag of dialysate) is recommended. Once equilibrium or steady state is achieved, the dialysate concentration will be comparable to the concentration of gentamicin in the plasma. Despite a more rapid transfer of drug into the plasma because of increased permeability of the peritoneal membrane in patients with peritonitis, there will still be a substantial lag time before steady state is reached. For more serious cases of peritonitis, concomitant systemic antibiotics should be given.

CASE 31-2, QUESTION 2: Is gentamicin eliminated by CAPD?

In general, most drugs are not well removed via CAPD. This is particularly true for drugs that are highly protein bound or for drugs with a large Vd. Gentamicin and other aminoglycosides, on the other hand, are effectively removed by CAPD because they have low protein binding and a small Vd. It is estimated that 10% to 50% of gentamicin is removed by CAPD.[61]

Acyclovir

RENAL CLEARANCE

CASE 31-3

QUESTION 1: D.M., a 28-year-old man with acquired immune deficiency syndrome, presents with a severe herpetic infection requiring IV acyclovir. Because of other complications associated with his human immunodeficiency virus (HIV) infection, D.M. has developed renal insufficiency during his hospital course. His SCr is 4.5 mg/dL, and his CrCl is 20 mL/minute. What are important considerations for dosing acyclovir in D.M. now, and also if he requires dialysis?

Acyclovir is used to prevent or treat a variety of viral infections, such as those caused by herpes simplex and varicella zoster viruses.[62] It is cleared primarily by the kidneys, with approximately 70% to 80% excreted unchanged in the urine. Dosage adjustment is necessary in patients with renal disease.[19,63] Renal tubular secretion in addition to filtration contributes to the elimination of acyclovir, which explains why the renal clearance of acyclovir is about 3 times greater than the estimated CrCl.

Acyclovir also can precipitate in the renal tubules and exacerbate D.M.'s renal failure. This is more likely to occur when high doses are infused too rapidly to patients with renal dysfunction.[63] To minimize nephrotoxicity, the patient should be adequately hydrated to maintain good urine flow, and the acyclovir dose should be infused over the course of 1 hour. Nephrotoxicity is usually reversible on discontinuation of the drug or reduction of the dose. In addition, acyclovir-associated neurotoxicity correlates with elevated plasma concentrations, and further underscores the need for adequate dosage adjustments in patients with renal dysfunction.[64]

The clearance of acyclovir correlates with the CrCl according to the following relationship:

$$\begin{aligned} &\mathrm{Cl}_{\mathrm{acyclovir}} \text{ in mL/minute/1.73 m}^2 \\ &\quad = (3.4)(\text{CrCl in mL/minute/1.73 m}^2) + 28.7 \end{aligned} \qquad \text{(Eq. 31-25)}$$

In patients with normal renal function, the clearance of acyclovir ranges from 210 to 330 mL/minute; in patients with ESRD, the clearance is 29 to 34 mL/minute.[19,63,65] Although this change in clearance primarily results from decreased renal clearance of the drug, nonrenal clearance of acyclovir also decreases in these patients.[19,65] As a result, the elimination half-life increases significantly from approximately 3 hours in patients with normal kidney function to 20 hours in patients with ESRD. Therefore, doses should be reduced proportionately from a normal daily dose of 15 mg/kg body weight (5 mg/kg given every 8 hours) for serious herpes simplex infections to doses as low as 2.5 mg/kg/day (given as a single daily dose) in patients with ESRD.[66] Because D.M. has a CrCl of 20 mL/minute and an estimated $\mathrm{Cl}_{\mathrm{acyclovir}}$ of 97 mL/minute (approximately one-third of normal), a single daily dose of 5 mg/kg (one-third of normal) would be appropriate to treat this infection.

DIALYSIS

Acyclovir is moderately removed by conventional hemodialysis, with plasma concentrations decreasing by 60% after 6 hours of dialysis.[67] The elimination half-life on and off dialysis is 6 and 20 hours, respectively, whereas the dialysis clearance averages 80 mL/minute. Therefore, a supplemental dose of 2.5 mg/kg after dialysis is recommended to replace the amount of drug removed by hemodialysis. No data are available on the removal of acyclovir by high-flux hemodialysis.

EFFECT OF RENAL DYSFUNCTION ON METABOLISM

CASE 31-3, QUESTION 2: Does D.M.’s renal dysfunction affect the metabolism of acyclovir? Are there other drugs that are affected similarly?

Approximately 20% of acyclovir is cleared by nonrenal mechanisms.[19,65] The only significant metabolite that has been isolated is 9-carboxymethoxymethylguanine, which accounts for 9% to 14% of an administered dose. It is believed that this metabolite is a product of hepatic metabolism; however, the kidney may also play an important role.[19] Whether renal dysfunction alters hepatic metabolism or metabolic enzymes are present within the kidney is unclear. Renal tissue contains many of the same metabolic enzymes found in the liver. Mixed-function oxidases have been found in segments of the proximal tubule, whereas other metabolic processes, such as glucuronidation, acetylation, and hydrolysis, also occur within the kidney.[17,18,68]

Renal failure can affect hepatic metabolic enzyme activity and drug transporter function.[69,70] Most of these investigations were carried out in animals that had diminished microsomal, mitochondrial, and cytosolic enzyme activities. Renal dysfunction substantially alters the nonrenal clearance of certain antibiotics, such as ceftizoxime, cefotaxime, and imipenem,[71–74] as well as the benzodiazepines, diazepam and desmethyldiazepam.[75,76]

Tenofovir

CASE 31-3, QUESTION 3: D.M. also is being treated with tenofovir as part of antiretroviral regimen for his HIV disease. Will his tenofovir doses need to be adjusted?

DOSAGE ADJUSTMENT

Tenofovir is a nucleotide analog of adenosine monophosphate. Tenofovir undergoes activation by phosphorylation to the active form, tenofovir diphosphate. Tenofovir diphosphate inactivates HIV reverse transcriptase and HBV DNA polymerase by causing chain termination.[77] It is used as part of an antiretroviral regimen in the treatment of HIV infection and can also be used for the treatment of chronic hepatitis B infection.[78] Approximately 70% to 80% of tenofovir is excreted unchanged in the urine. The elimination half-life is approximately 17 hours, and the clearance is significantly reduced in the setting of renal dysfunction. Nephrotoxicity, including cases of acute renal failure and Fanconi syndrome (renal tubular injury and hypophosphatemia) have been reported. Organic transporters in the proximal tubule are believed to mediate nephrotoxicity.[79] The dose of tenofovir must be adjusted in the setting of kidney dysfunction to prevent accumulation, and the potential to worsen renal dysfunction. Tenofovir is also available in combination with other antiretrovirals in a single dose formulation for the treatment of HIV infection. The specific dosing recommendation should be consulted in the setting of renal dysfunction for tenofovir or the combination products.

HEMODIALYSIS

CASE 31-3, QUESTION 4: Is tenofovir significantly removed by dialysis?

Tenofovir is effectively removed by hemodialysis, with an extraction coefficient of approximately 54%. Approximately 10% of a 300 mg tenofovir dose is removed after 4 hours of hemodialysis. The recommended dose of tenofovir is 300 mg orally every 7 days (after approximately 12 hours of hemodialysis or three 4-hour dialysis sessions).[78,80]

Penicillin

DOSAGE ADJUSTMENT

CASE 31-4

QUESTION 1: T.H., a 57-year-old, 85-kg man with chronic kidney disease secondary to poorly controlled hypertension, presents to the ED with a 24-hour history of fever (39°C), altered mental status, nausea, and vomiting. On physical examination he is found to have nuchal rigidity and a positive Brudzin´ski sign. Laboratory analysis reveals the following:

WBC count, 22,000/µL with 89% neutrophils
BUN, 45 mg/dL
SCr, 4.4 mg/dL

A lumbar puncture yields cerebrospinal fluid (CSF) with a WBC count of 2,000/µL (90% polymorphonuclear neutrophils), a glucose concentration of 36 mg/dL, and a protein concentration of 280 mg/dL. Gram-positive diplococci are seen on CSF smear. A diagnosis of meningococcal meningitis is made, and potassium penicillin G is ordered. What dose should be used?

Meningococcal meningitis can be treated with 20 to 24 million units of IV penicillin G in patients with normal renal function. As with many β-lactam antibiotics, penicillin is primarily excreted unchanged in the urine with little or no hepatic metabolism. Thus, the elimination half-life, which averages less than 1 hour in patients with normal kidney function, increases to 4 to 10 hours in patients with ESRD.[81–83]

Methods to modify the dose of penicillin in renal insufficiency have been developed by numerous investigators. The clearance of penicillin correlates closely with CrCl according to the following equation[83]:

$$\mathrm{Cl_{pen}\ in\ mL/minute} = 35.5 + 3.35\ \mathrm{CrCl\ in\ mL/minute} \qquad \text{(Eq. 31-26)}$$

This correlation is based on data from patients with varying degrees of renal impairment.

An equation to estimate the total daily dose for patients with renal failure to achieve serum levels similar to those produced by high-dose penicillin (20–24 million units/day) in patients with normal renal function has been developed for patients with an estimated CrCl of less than 40 mL/minute. The dose for T.H. should be given in equal divided doses at 6- or 8-hour intervals:

$$\text{Dose}_{\text{pen}} \text{ in million units/day} = 3.2 + (\text{CrCl}/7) \quad \text{(Eq. 31-27)}$$

Using the Cockcroft–Gault method, T.H.'s CrCl is approximately 20 mL/minute. Therefore, his daily dose of penicillin should be 6 million units. A dose of 1 million units every 4 hours would be appropriate for T.H. Penicillin G is often given as the potassium salt (penicillin G potassium), which contains approximately 1.7 mEq of potassium per 1 million units of penicillin. Accumulation of potassium due to renal impairment may lead to hyperkalemia. Penicillin G sodium is an alternative formulation that would be appropriate.

As is true for many agents, these dosing recommendations are empiric and based on pharmacokinetic principles for patients in renal failure. These recommendations have not been subjected to carefully designed clinical trials that establish therapeutic efficacy. Therefore, other factors that can influence host response also should be considered when designing an individualized therapeutic regimen. These include the host's immune status, the presence of other medical conditions, microbial sensitivity patterns, and changes in pharmacokinetic disposition (e.g., concomitant liver disease, fluid overload, dehydration).

PENICILLIN-INDUCED NEUROTOXICITY

CASE 31-4, QUESTION 2: The prescriber fails to consider T.H.'s renal dysfunction when he orders penicillin, and begins a dose of 4 million units every 4 hours. Four days later, T.H. is encephalopathic (confused, disoriented, and difficult to arouse), with some twitching noted on the right side of his face. Are these toxic symptoms associated with high-dose penicillin? What predisposing factors may contribute to this neurotoxicity?

T.H. is experiencing signs of neurotoxicity that are consistent with elevated penicillin concentrations in the plasma and CSF. Penicillin usually produces few serious adverse effects. When large doses are used in patients with renal impairment, toxic symptoms such as those exhibited by T.H. can result. Signs and symptoms of penicillin-induced CNS toxicity include myoclonus, complex or generalized seizure activity, and encephalopathy progressing to coma.[39,40]

Predisposing Factors

T.H.'s renal dysfunction predisposes him to penicillin-induced neurotoxicity. In a review of 46 cases of penicillin-associated neurotoxicity, decreased renal function was present in 35 patients.[40] Several possible explanations for this observation exist. Penicillin accumulates in patients with renal failure. The binding of acidic drugs (such as penicillin) to albumin is decreased, resulting in an increased fraction of free or active drug that can pass into the CSF. Alterations in the blood–brain barrier have been observed in uremic patients, which can lead to further increases in CSF drug levels.[39] High plasma concentrations of penicillin per se may contribute to changes in the blood–brain barrier permeability of this drug.[39] All these factors, together with the increased sensitivity of patients with renal failure to centrally acting agents, make CNS toxicity more likely. Previous neurotrauma, history of seizures, elderly age, and concurrent drugs that lower the seizure threshold can also contribute to neurotoxicity. As with penicillin, the carbapenem antibiotic combination, imipenem–cilastatin, is associated with a higher incidence of seizures in patients with renal dysfunction.[84,85] Other β-lactam antibiotics such as ceftazidime, cefepime, and piperacillin/tazobactam have also been associated with seizures.[86,87]

Antipseudomonal Penicillins

PIPERACILLIN

CASE 31-5

QUESTION 1: M.H., a 44-year-old, 70-kg woman with acute nonlymphocytic leukemia, was admitted to the oncology ward for placement of a Hickman catheter for her chemotherapy. Seven days after treatment with cytarabine and daunorubicin, her temperature spiked to 39.4°C. Other physical findings consistent with sepsis included a blood pressure of 102/68 mm Hg, pulse rate of 112 beats/minute, and a respiratory rate of 27 breaths/minute. M.H. is neutropenic with a WBC count of 1,400/μL (3% polymorphonuclear leukocytes, 70% lymphocytes, and 22% monocytes). Her platelet count is 16,000/μL. M.H. also has renal dysfunction as reflected by an SCr and BUN of 2.6 and 38 mg/dL, respectively. Empiric therapy for sepsis is started with tobramycin, piperacillin/tazobactam, and vancomycin. How should piperacillin/tazobactam be dosed in M.H.?

Piperacillin is an antipseudomonal penicillin that is often used with an aminoglycoside to treat serious infections caused by gram-negative organisms.[88] Piperacillin is commonly given as a combination with tazobactam, a β-lactamase inhibitor.[89] In patients with normal renal function, piperacillin is primarily excreted unchanged by the kidney with a clearance of 2.6 mL/minute/kg, and a half-life of approximately 1 hour.[90,91] Doses of piperacillin/tazobactam can be as high as 4.5 g every 6 hours for the treatment of serious Pseudomonas species infections. In patients with ESRD, mean piperacillin clearance and half-life values are 0.7 mL/minute/kg and 3.3 hours, respectively.[90–92] Although these parameters are significantly different, they are less than those expected for a drug primarily cleared by the kidneys, suggesting that some other compensatory mechanism for elimination must be present. Piperacillin is partially cleared by biliary excretion, a route of elimination that is increased in patients with renal failure.[92,93] Therefore, aggressive dosage reductions in M.H. are unnecessary. An appropriate dose of piperacillin/tazobactam for M.H. would be 3.375 g every 8 hours. Widely used drug references such as Facts and Comparisons can be used for dosing guidelines for drugs commonly used in patients with renal failure.[45]

Vancomycin

PHARMACOKINETIC DOSAGE CALCULATIONS

CASE 31-5, QUESTION 2: In addition to the aforementioned regimen for M.H., vancomycin therapy is initiated at 500 mg every 24 hours to cover the possibility of an infection resistant to antistaphylococcal penicillins, such as nafcillin. Is this an appropriate dosing regimen for M.H.?

Vancomycin is a bactericidal antibiotic with excellent activity against most gram-positive organisms such as methicillin-resistant Staphylococcus aureus and Streptococcus species, including some isolates of Enterococcus species. It is used empirically in febrile neutropenic patients because the incidence of infection secondary to resistant organisms is much greater in this patient population. However, cases of vancomycin-resistant enterococci have emerged at rates as high as 50%, raising concern and reducing its empiric use.[94]

Vancomycin is poorly absorbed by the oral route and must be administered IV when used to treat systemic infections. As with many other antibiotics, vancomycin primarily is cleared by the kidneys.[95] Significant toxicities have been associated with elevated serum concentrations, making careful dosing modification in renal failure necessary.[96]

As with the aminoglycosides, pharmacokinetic calculations can be used to individualize a dosing regimen to produce the desired peak and trough plasma levels. Unlike the aminoglycosides, the therapeutic range for vancomycin is less clear. Normally, doses are designed to achieve peak levels of 25 to 40 mg/L and trough levels of 10 to 15 mg/L.[97,98] The correlation between vancomycin toxicity (e.g., ototoxicity) and plasma levels is not well defined. Some clinicians have suggested, however, that plasma levels of 80 mg/L or more may correlate with auditory dysfunction.

Vancomycin has an elimination half-life of 3 to 9 hours in patients with normal renal function.[99] This increases to 129 to 189 hours in patients with ESRD.[100–102] Using pharmacokinetic principles and considering that the plasma clearance of vancomycin is approximately 60% to 70% of CrCl[97] and the Vd averages 0.7 L/kg,[97,99,103] the estimated Vd_{vanco} and Cl_{vanco} can be calculated using the following equation:

$$
\begin{aligned}
Cr_{Cl} &= 30.5\ \text{mL/minute (calculated from} \\
&\quad \text{Eq. 31-5)} \\
Cl_{vanco} &= (0.65)(CrCl) \\
&= (0.65)(30.5\ \text{mL/minute}) \\
&= 19.8\ \text{mL/minute or rounded} \\
&\quad \text{off to 1.2 L/hour}
\end{aligned}
\qquad \text{(Eq. 31-28)}
$$

$$\begin{aligned} \mathrm{Vd}_{\mathrm{vanco}} &= (0.7\ \mathrm{L/kg})(\text{body weight}) \\ &= (0.7\ \mathrm{L/kg})(70\ \mathrm{kg}) \\ &= 49\ \mathrm{L} \end{aligned} \qquad \text{(Eq. 31-29)}$$

Based on estimated values for $\mathrm{Cl}_{\mathrm{vanco}}$ and $\mathrm{Vd}_{\mathrm{vanco}}$, the elimination rate constant can be calculated using the following equation:

$$\begin{aligned} \mathrm{Kd} &= \frac{\mathrm{Cl}_{\mathrm{vanco}}}{\mathrm{Vd}_{\mathrm{vanco}}} \\ &= \frac{1.2\ \mathrm{L/hour}}{49\ \mathrm{L}} \\ &= 0.024\ \mathrm{hour}^{-1} \end{aligned} \qquad \text{(Eq. 31-30)}$$

$$\begin{aligned} \mathrm{Cp} &= \frac{\dfrac{\mathrm{Dose}}{\mathrm{Vd}_{\mathrm{vanco}}}}{1 - e^{-\mathrm{Kd}t}} \\ &= \frac{\dfrac{500\ \mathrm{mg}}{49\ \mathrm{L}}}{1 - e^{-(0.024\ \mathrm{hour}^{-1})(24\ \mathrm{hours})}} \\ &= 23\ \mathrm{mg/L} \end{aligned} \qquad \text{(Eq. 31-31)}$$

$$\begin{aligned} Cp_{\text{trough}} &= Cp_{\text{peak}}\,(e^{-Kdt}) \\ &= 23\ \text{mg/L}\,(e^{-(0.024/\text{hour}^{-1})(24\ \text{hours})}) \\ &= 13\ \text{mg/L} \end{aligned} \tag{Eq. 31-32}$$

Because M.H.'s estimated peak concentration is less than 40 mg/L and her trough falls within the range of 10 to 15 mg/L, the starting dose of 500 mg every 24 hours is appropriate for M.H.

Routine monitoring of plasma vancomycin concentrations in patients with normal renal function is controversial because the likelihood that toxicity will develop in this group is relatively low. However, in patients with renal failure, such as M.H., it is advisable to measure vancomycin levels several days after initiation of therapy to ensure that they are within an acceptable range.[99,101,102,104] This is prudent if an extended course of therapy is anticipated. Vancomycin is usually infused over the course of 60 minutes.

HEMODIALYSIS OF VANCOMYCIN

CASE 31-5, QUESTION 3: M.H.'s renal function begins to deteriorate to the point where she requires hemodialysis. How should her regimen now be altered?

Patients with ESRD may have measurable vancomycin levels for up to 3 weeks after a single dose despite conventional hemodialysis.[102] This suggests that the ability of these patients to eliminate vancomycin is minimal and that little of the drug is removed by conventional hemodialysis. The elimination half-life for vancomycin in these individuals averages 5 to 7 days, which is consistent with a residual vancomycin clearance of 3 to 4 mL/minute.[100–102] Only about 5% of vancomycin is metabolized hepatically in patients with normal renal function.

Conventional hemodialysis removes about 7% of vancomycin during a typical 4-hour dialysis run.[105] The elimination half-life on and off dialysis and plasma levels of the drug before and after hemodialysis do not differ significantly. The poor removal of vancomycin by conventional hemodialysis is attributable to its large MW of 1,400.

Patients receiving conventional hemodialysis are typically given a single, 1-g dose every 7 to 10 days.[99,102,104] Based on M.H.'s estimated Vd of 49 L, this dose will produce an initial peak plasma level of approximately 20 mg/L. If vancomycin is administered weekly, steady-state peak and trough levels of 40 and 16 mg/L, respectively, would be predicted.

Vancomycin is removed to a greater extent by high-flux hemodialysis than by conventional hemodialysis. As a result, more frequent dosing is necessary to maintain therapeutic vancomycin concentrations. High-flux dialysis clearance of vancomycin using the Fresenius polysulfone dialyzer is 45 to 160 mL/minute and varies with membrane surface area.[60,106] Up to 50% of a dose of vancomycin is removed in 4 hours by high-flux hemodialysis compared with 6.9% using conventional dialysis. A rebound phenomenon after dialysis suggests that the total amount of drug removed may be less than initially reported.[107,108] In any case, the efficiency of high-flux procedures in removing vancomycin is greater than that of conventional dialysis. Therefore, plasma levels should be monitored carefully in these patients, and the necessity for postdialysis replacement doses of around 500 mg (~10–15 mg/kg) should be anticipated.

Caspofungin

DOSING

CASE 31-5, QUESTION 4: M.H. continues to be febrile despite her triple antimicrobial regimen. Caspofungin is started empirically for potential fungal infections. In addition, pentamidine is begun to cover Pneumocystis jirovecii pneumonia. How should caspofungin be administered in patients such as M.H. with renal dysfunction?

HEMODIALYSIS OF CASPOFUNGIN

Caspofungin is an echinocandin antifungal agent that is slowly metabolized by hydrolysis and N-acetylation, with little being excreted unchanged in the urine.[109] Caspofungin is not removed significantly by hemodialysis or continuous hemofiltration. No dosage adjustment is necessary in patients with renal failure or on renal replacement therapy.[110] The maintenance dose needs to be reduced in the setting of moderate liver failure however.

CASE 31-5, QUESTION 5: What factors need to be considered when other antifungal agents are used in patients with kidney disease?

Amphotericin B is a polyene antifungal agent that has activity against a wide variety of fungi. Amphotericin B is extensively distributed into the peripheral tissue, and has a long elimination half-life of approximately 15 days.[111,112] There is no significant change in the disposition of amphotericin B in patients with liver or kidney disease. The utility of amphotericin B has been limited due to its nephrotoxicity.[113] Lipid-based formulations are associated with a lower incidence of nephrotoxicity and other systemic side effects.[114] Triazole antifungal agents (e.g., fluconazole, posaconazole, voriconazole) or an echinocandin class (e.g., anidulafungin, caspofungin, micafungin) are alternative choices that are not potentially nephrotoxic, nor do they need to be dose adjusted in the setting of renal dysfunction (with the exception of fluconazole). The oral as opposed to the IV formulation of voriconazole and posaconazole should be used in the setting of renal dysfunction or for patients with a CrCl of less than 50 mL/minute to prevent accumulation of sulfobutyl ether β-cyclodextrin, the solvent vehicle found in the IV formulation.[115]

Cefazolin

PERITONEAL DIALYSIS

CASE 31-6

QUESTION 1: M.J. is a 65-year-old woman with chronic kidney disease awaiting a kidney transplant. She has been managed with PD for the past 8 years. She presents with a cloudy effluent and abdominal pain. Analysis of the effluent reveals a WBC count of 323/μL and gram-positive cocci and clusters on Gram stain. The patient has a history of S. aureus peritonitis that was readily treated with cefazolin previously. The patient has no allergies, and weighs 52 kg. How should M.J.'s PD-related infection be managed?

Gram-positive cocci such as S. aureus are common causes of PD-related infections. The selection of empiric antibiotics should be made based on the patient's and program's history of microorganisms and sensitivities. A first-generation cephalosporin such as cefazolin would be a reasonable choice for M.J. Programs with a high rate of methicillin-resistant organisms should use vancomycin.

IP antibiotics can be given with each exchange (continuous dosing). In this situation, a single 500-mg/L loading dose of cefazolin is given followed by a maintenance dose of 125 mg/L with subsequent exchanges. Antibiotics can also be given intermittently (once daily per exchange). With intermittent dosing, the antibiotic-containing dialysis solution should dwell for at least 6 hours to allow for adequate absorption. Cefazolin 15 mg/kg (rounded off to 750 mg) is typically given in one exchange. For patients on automated PD, the dose of cefazolin is 20 mg/kg every day in a long-day dwell. For patients with residual renal function (e.g., >100 mL/day of urine output), empirically, the dose is increased by 25%. The management of PD-related infections and dosing of various antibiotics is discussed in the International Society for Peritoneal Dialysis guidelines.[116]

Phenytoin

PROTEIN BINDING

CASE 31-7

QUESTION 1: R.S., a 24-year-old man with ESRD from rapidly progressive glomerulonephritis, is treated by hemodialysis 3 times weekly. He has a 7-year history of generalized tonic–clonic seizures and has been treated with phenytoin. He presents to the ED after having had a seizure lasting about 5 minutes. His mother states that he ran out of phenytoin 4 weeks ago. Because his plasma phenytoin concentration on admission was less than 2.5 mg/L, R.S. is given an IV loading dose of fosphenytoin: 15 mg/kg in 30 minutes. Additional admission laboratory work includes the following:

SCr, 8.6 mg/dL
BUN, 110 mg/dL

Potassium, 5.4 mEq/L
Calcium, 9 mg/dL
Albumin, 2.9 g/dL

Eight hours after administration, his phenytoin level is 5 mg/L. Is this level subtherapeutic?

R.S. has severe renal disease, which will affect the total (bound plus free) phenytoin concentration achieved and how this concentration is interpreted. Decreased plasma protein binding will result in lower measured total phenytoin concentrations, and the calculated apparent Vd may increase. In patients with normal renal function, approximately 90% of the measured phenytoin is bound to albumin, and 10% is free. The free fraction of phenytoin is increased to about 20% to 25% in patients with uremia.[11,117–121] Because the free fraction for phenytoin is increased in patients with uremia, lower plasma concentrations will produce therapeutic effects that will be equivalent to those produced by higher phenytoin concentrations in patients with normal renal function.[8,122] Phenytoin is an acidic drug that is bound primarily to albumin. A number of mechanisms have been proposed that account for the decreased binding, including (a) decreased albumin concentration, (b) accumulation of uremic by-products that displace acidic drugs from their binding sites, and (c) alteration in the conformation or structure of albumin in uremic patients, resulting in a reduced number of binding sites or decreased affinity for drugs (see Chapter 60, Seizure Disorders). Other acidic drugs with altered protein binding in renal disease are listed in Table 31-1.

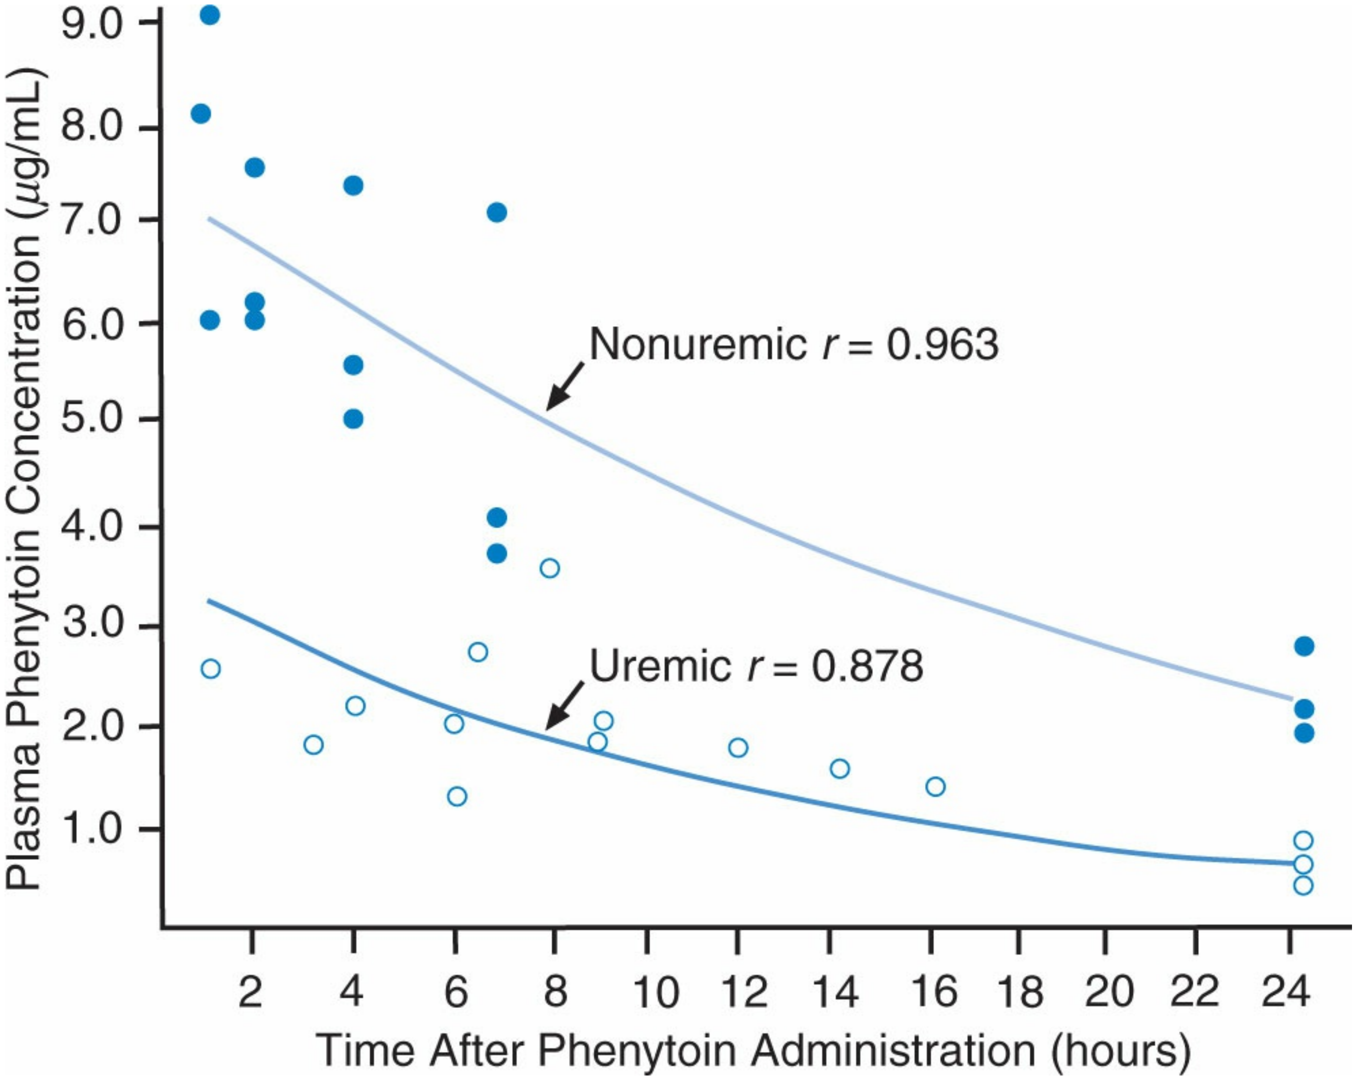

Figure 31-2 Plasma phenytoin concentrations in uremic (°) and nonuremic (•) patients after 250 mg of intravenous (IV) phenytoin. (Reprinted with permission from Letteri JM et al. Diphenylhydantoin metabolism in uremia. N Engl J Med. 1971;285:648. Copyright © 2001 Massachusetts Medical Society. All rights reserved.)

Figure 31-2 illustrates changes in phenytoin levels when uremic and nonuremic patients are given equivalent doses.[123]

The following equation should be used to correct for R.S.'s altered binding owing to his renal dysfunction and hypoalbuminemia[120]:

$$Cp_{\text{Normal Binding}} = \frac{Cp'}{(0.48)(1-\alpha)\left(\dfrac{P'}{P_{NL}}\right)+\alpha} \qquad \text{(Eq. 31-33)}$$

where Cp′ is the measured plasma concentration reported by the laboratory, and $Cp_{\text{Normal Binding}}$ is the corrected plasma concentration that would be seen if the patient had normal renal function and normal albumin. Alpha (α) is the normal free fraction (0.1), P′ is the patient's serum albumin, and P_{NL} is normal albumin (4.4 g/dL). The factor 0.48 was derived from patients on hemodialysis and represents the decreased affinity of phenytoin for albumin.

For R.S., a total plasma phenytoin concentration of 5 mg/L is comparable to 13 mg/L in a patient without renal failure. Because this falls within the phenytoin's therapeutic range of 10 to 20 mg/L, his measured level is not subtherapeutic.

The factor 0.48 should be used only to estimate changes in protein binding for patients with ESRD receiving hemodialysis. Data for patients with moderate renal disease are limited, and it is unclear what changes exist in the binding of phenytoin to albumin.[118] For patients with normal or moderate renal impairment, the following equation should be used only if the serum albumin is low; the factor 0.48 should be omitted:

$$Cp_{\text{Normal Binding}} = \frac{Cp'}{(1-\alpha)\left(\frac{P'}{P_{NL}}\right)+\alpha} \quad \text{(Eq. 31-34)}$$

Fosphenytoin, a prodrug of phenytoin, does not need to be dissolved in propylene glycol, and therefore can be administered more quickly. This offers an important advantage for seizures that must be controlled quickly. In patients with renal failure, the conversion of fosphenytoin to phenytoin was equally efficient in patients with renal disease and healthy subjects.[124] Once fosphenytoin is converted to phenytoin, the impact of renal disease on protein binding is expected to be similar to that seen with phenytoin and thus the same considerations should be made for patients with renal failure.

EFFECT OF RENAL FAILURE ON METABOLIZED DRUGS

Meperidine

CASE 31-8

QUESTION 1: F.G., a 56-year-old woman, is admitted for a cervical laminectomy. She has a history of chronic kidney disease (CrCl 20 mL/minute) and arrhythmias that are treated with amiodarone. Her admission laboratory values are as follows:

SCr, 4.4 mg/dL
BUN, 66 mg/dL
Hematocrit, 34%
Hemoglobin, 12.6 g/dL

After surgery, she complains of severe pain and is treated with meperidine 50 to 100 mg intramuscularly every 3 to 4 hours. Three days postoperatively, F.G. experiences a generalized tonic–clonic seizure. She has no history of seizures. What might be responsible for this sudden event?

Meperidine is a narcotic analgesic commonly used to control acute pain. It is metabolized hepatically via N-demethylation to normeperidine, a metabolite known to accumulate in renal insufficiency.[15,125] Although meperidine has both CNS excitatory and depressant properties, normeperidine is a very potent CNS stimulant that can cause seizures in patients with renal failure who are receiving multiple doses of the parent drug.[126] Patients with renal dysfunction given merperidine experience more neurologic effects.[126] Because the renal clearance of normeperidine correlates significantly with CrCl, renal dysfunction can lead to its accumulation, resulting in neurologic toxicity. The normeperidine to meperidine plasma concentration ratio was consistently higher in patients with renal failure, averaging 2.0 compared with a mean of 0.6 for patients with good renal function.[126] Table 31-3 lists examples of additional drugs that have active or toxic metabolites that may accumulate in renal disease.

Narcotic Analgesics

CASE 31-8, QUESTION 2: Are the pharmacokinetics or pharmacodynamics of other narcotic analgesics altered in patients with renal insufficiency?

MORPHINE

The pharmacokinetic disposition of morphine does not appear to be altered in patients with renal failure[127]; however, its active metabolite, morphine-6-glucuronide, as well as its principal metabolite, morphine-3-glucuronide, do accumulate in renal disease. The elimination half-life of morphine-6-glucuronide increases from 3 to 4 hours in normal subjects to 89 to 136 hours in subjects with renal failure.[128] This metabolite penetrates the blood–brain barrier more readily, has a greater affinity for CNS receptors, and has analgesic activity that is 3.7 times greater than morphine.[129] Therefore, accumulation of morphine-6-glucuronide may be responsible for the morphine-induced narcosis reported in patients with severe renal disease.[32,33]

CODEINE

Other analgesics that have been associated with CNS toxicity in patients with renal failure include codeine, propoxyphene, and dihydrocodeine.[125] The disposition of orally administered codeine does not appear to be altered in renal failure; however, there have been case reports of codeine-induced narcosis.[130] Although the dose of codeine did not exceed 120 mg/day, CNS and respiratory depression persisted for up to 4 days after discontinuing codeine and initiating naloxone administration. The elimination half-life of codeine is prolonged in patients on chronic hemodialysis. Although the Vd of codeine was twice as large, the total clearance was not significantly decreased.[131] A lower initial dose should be used because codeine is metabolized to morphine.

Table 31-3

Drugs with Active or Toxic Metabolites Excreted by the Kidney

Drug	Metabolite
Acetohexamide	Hydroxyhexamide
Allopurinol	Oxypurinol
Bupropion	Threo/erythro-hydrobupropion
Cefotaxime	Desacetylcefotaxime
Chlorpropamide	Hydroxy metabolites
Clofibrate	Chlorphenoxyisobutyrate
Cyclophosphamide	4-Ketocyclophosphamide
Daunorubicin	Daunorubicinol
Meperidine	Normeperidine
Methyldopa	Methyl-O-sulfate-α-methyldopamine
Midazolam	α-Hydroxymidazolam
Morphine	Morphine-3-glucuronide
	Morphine-6-glucuronide
Phenylbutazone	Oxyphenbutazone
Primidone	Phenobarbital
Procainamide	N-acetylprocainamide (NAPA)
Propoxyphene	Norpropoxyphene
Rifampicin	Deacetylated metabolites
Sodium nitroprusside	Thiocyanate
Sulfonamides	Acetylated metabolites
Tramadol	O-Demethyl-N-demethyltramadol

HYDROMORPHONE

Hydromorphone is metabolized in the liver to hydromorphone-3-glucuronide, dihydroisomorphone, dihydromorphine, and small amounts of hydromorphone-3-sulfate, norhydromorphone, and nordihydroisomorphone.[132] All metabolites that are eliminated are excreted by the kidneys. Hydromorphone can be used in patients with renal failure; however, smaller initial doses may be warranted.[131]

Enoxaparin

CASE 31-8, QUESTION 3: Because F.G. is not ambulating well after her surgery, her physician would like to initiate deep vein thrombosis prophylaxis with enoxaparin. Are there any dosing considerations for enoxaparin in this patient?

Enoxaparin is a low MW heparin that is used to prevent and treat various thromboembolic disorders, such as deep venous thrombosis, unstable angina, and non–Q wave myocardial infarction. The kidneys play a major role in the clearance of enoxaparin,[133] and a higher incidence of bleeding complications is associated

with the use of enoxaparin in patients with renal dysfunction.[134] The elimination half-life of enoxaparin is prolonged in patients with ESRD, although the other pharmacokinetic parameters are similar to those in healthy subjects.[135,136] The increased incidence of bleeding complications cannot be completely attributed to pharmacokinetic changes, but may also be related to the effects of enoxaparin on antifactor IIa and antithrombin III, as well as the effects of uremia on hemostasis.[137]

Enoxaparin should be used cautiously in patients with a CrCl less than 30 mL/minute, with a recommended lower dosage of 30 mg subcutaneously daily. Although monitoring of the anticoagulant effect by anti-Xa activity is not necessary in clinically stable patients, it may be warranted in patients with renal dysfunction as well as in those who have other factors that may increase the risk of bleeding complications.

ASSESSING RENAL FUNCTION IN THE ELDERLY

Renal function declines physiologically with advancing age and as the result of comorbidities such as hypertension and diabetes.[138] This decrease in renal function can have significant consequences on drug excretion, metabolism, and the potential for adverse drug reactions, particularly in the elderly population that is often prescribed multiple medications.[139] Antithrombotic and antidiabetic drugs are high-risk medications that are often implicated as a cause for hospitalizations due to adverse drug events in elderly patients.[140] Sulfonylurea antidiabetic agents such as glyburide that are eliminated primarily by the kidneys can lead to prolonged hypoglycemia in patients with decreased renal function.[141] In addition, metformin should be used with caution in patients with kidney dysfunction due to the increased risk for lactic acidosis.

Formulas that estimate renal function use the serum creatinine. In elderly adults, a low serum creatinine may not always be indicative of normal renal function. Older adults tend to have lower muscle mass than younger people, and a low serum creatinine may not be indicative of normal renal function, but rather reduced muscle mass. Differences in the estimated GFR between the MDRD and Cockcroft–Gault formulas may result in discordant dosing recommendations in an elderly population.[142]

This highlights the importance of obtaining a comprehensive medication history, assessment of the patient's renal function, and evaluation of the available drug-information resources for appropriate dosing recommendations for each patient.

SUMMARY

The kidneys play a vital role in maintaining homeostasis by regulating the excretion of water, electrolytes, and metabolic by-products. In addition, the kidneys are the primary route of elimination for many drugs. Pharmacokinetic changes, such as altered bioavailability, protein binding, drug distribution, and elimination, can occur with many drugs in patients with renal failure. Pharmacodynamic changes, such as altered sensitivity or response to medications, can also occur in this patient population. Renal replacement therapies, such as hemodialysis, CAPD, and CVVH, will aid in the removal of fluid, electrolytes, and metabolic by-products in drugs as well. Data from clinical trials provide valuable information about the disposition of drugs in patients with renal failure. Pharmacokinetic principles should be applied when appropriate to determine the optimal dose of drugs for patients with renal failure.

Drug Hypersensitivity Reactions

Greene Shepherd and Justinne Guyton

CORE PRINCIPLES		CHAPTER CASES
1	Drug allergies are a subset of adverse drug reactions that are usually mediated by the immune system. Although typically unpredictable, there are several factors known to influence the frequency of allergic reactions including age, sex, genetics, prior drug exposure, and drug dose and route. A detailed drug history is key to assisting in the diagnosis of a drug allergy.	**Case 32-1 (Questions 1, 2)** **Table 32-1**
2	Skin testing for allergy to penicillin is an important diagnostic tool that assists in determining whether or not a patient is truly allergic to this class of drug. Patients presenting with a history of penicillin allergy but who have a negative penicillin scratch test and a negative intradermal test can be safely given β-lactam antibiotics.	**Case 32-1 (Question 3)** **Table 32-4**
3	There are varying degrees of cross-reactivity between various β-lactam antibiotics. Understanding the frequency of cross-reactivity is important in making treatment decisions if skin testing is not available. The frequency of cross-reaction between penicillins and cephalosporins has been reported to be 5% to 15%, but it is likely much lower. The risk of a cephalosporin reaction in a patient with a penicillin allergy decreases with increasing cephalosporin generation, being lowest with the third- and fourth-generation drugs. The frequency of cross-reaction between penicillins and carbapenems or monobactams appears to be very low (approximately 1%).	**Case 32-1 (Question 4)**
ANAPHYLAXIS		
1	Anaphylaxis is a serious allergic reaction that has a rapid onset and might cause death. It is caused by the rapid release of immune mediators from tissue mast cells and peripheral blood basophils. Symptoms such as pruritus of the hands, feet, and groin; flushing; lightheadedness; hypotension; tachycardia; and difficulty breathing can begin within minutes of exposure to the precipitating agent, which is most commonly foods, insect stings, and drugs. Prompt recognition and treatment are critical to ensure a favorable outcome.	**Case 32-2 (Questions 1, 2)** **Table 32-2**
2	Epinephrine is the drug of choice for treatment of anaphylaxis and should be given immediately upon suspicion of an anaphylactic reaction.	**Case 32-2 (Question 3)** **Table 32-5**

	Epinephrine should be given intramuscularly into the lateral thigh as often as every 5 minutes to treat symptoms. Intramuscular injection is preferred over the subcutaneous and intravenous (IV) routes because of rapid absorption and ease of administration. The patient should be placed in the Trendelenburg position and second-line treatments including oxygen, IV fluids, and a nebulized β-agonist initiated as needed. Antihistamines and corticosteroids are also commonly used to treat anaphylaxis although there are no data showing an impact on outcome from these therapies.	

p. 679

p. 680

GENERALIZED REACTIONS

①	Generalized hypersensitivity reactions can manifest in a number of ways including drug fever, serum sickness, hemolytic anemia, vasculitis, and autoimmune disorders. Specific organ systems such as the lungs, liver, kidneys, and hematopoietic system can also be the target of allergic drug reactions.	**Case 32-3 (Question 1), Case 32-4 (Questions 1, 2), Case 32-5 (Questions 1, 2) Tables 32-6, 32-7, 32-8**

PSEUDOALLERGIC REACTIONS

①	Pseudoallergic reactions are drug reactions that exhibit clinical signs and symptoms of an allergic response but are not immunologically mediated. Pseudoallergic reactions can be relatively benign (such as red man syndrome from vancomycin) or potentially life-threatening, clinically resembling immune-mediated anaphylaxis as from radiocontrast media. Several drugs are associated with pseudoallergic reactions including aspirin and nonsteroidal anti-inflammatory drugs, opiates, angiotensin-converting enzyme inhibitors, and injectable iron products.	**Case 32-6 (Questions 1, 2, 5), Case 32-7 (Question 1) Tables 32-9**
②	The management of pseudoallergic reactions is the same as for true allergic reactions.	**Case 32-6 (Questions 3, 4), Case 32-7 (Question 2)**

PREVENTION AND MANAGEMENT OF ALLERGIC REACTIONS

①	The keys to preventing an allergic reaction in a patient with history of allergy are a good description of the reaction and its causes, distinguishing between drug allergy and drug intolerance, and good documentation and communication of the reaction.	**Case 32-1 (Questions 1, 2), Case 32-8 (Question 1)**
②	In some cases, it is necessary to treat a patient with a drug to which they have a significant allergic reaction. To accomplish this, the process of tolerance induction (or desensitization) may be used. Tolerance induction starts with administration of a sub-allergenic dose of the drug to which a patient is allergic and the progressive administration of larger doses with the goal of modifying the patient's response. Once tolerance has been successfully induced, the patient must remain on the drug to maintain the state of tolerance. Tolerance induction should not be used in patients with a history of a severe non–IgE-mediated reaction such as hepatitis, hemolytic anemia, Stevens–Johnson syndrome, or toxic epidermal necrolysis.	**Case 32-9 (Questions 1, 2, 4)**

③ The oral route of tolerance induction is preferred over the IV route. Patients may experience a mild reaction during desensitization, although severe reactions are rare. Even after successful desensitization, patients may experience an allergic reaction during full dose therapy.	**Case 32-9 (Questions 2, 3)**
④ A graded drug challenge (also called test dosing) is a process of giving subtherapeutic doses of a drug to a patient to determine if they are allergic. A graded drug challenge generally uses larger starting doses than tolerance induction and involves fewer steps. Graded drug challenge may be appropriate in patients with a distant or unclear history of drug allergy, when the reaction seems minor or when diagnostic testing is unavailable, or in cases where cross-reactivity is expected to be low. Graded challenge should not be used in patients with a history of a severe non-IgE–mediated reaction such as hepatitis, hemolytic anemia, Stevens–Johnson syndrome, or toxic epidermal necrolysis.	**Case 32-9 (Question 1)**

Adverse drug reactions occur in up to 20% of hospitalized patients and up to 25% of ambulatory patients. Studies have found that up to 6% of all hospitalizations are caused by an adverse drug event. Immunologically mediated adverse drug reactions (also commonly referred to as drug allergy or hypersensitivity) account for about one-third of all adverse drug reactions and may affect 10% to 15% of hospitalized patients.[1–4] In one study of more than 36,000 hospitalized patients, 731 adverse events were identified, with 1% being severe, life-threatening, allergic reactions.[5] The potential morbidity and mortality associated with allergic drug reactions can be significant.

DEFINITION

Adverse drug reactions resembling an immune response are called drug hypersensitivity reactions (DHRs). True drug allergies show evidence of either drug-specific antibodies or T-cells.[1] Clinically, DHRs are commonly classified as immediate or delayed depending on their onset during treatment. Immediate reactions occur within a few hours of exposure and usually are mediated by IgE. Delayed reactions will occur a few days after starting therapy and are typically mediated by T-cells. See Table 32-1.

Table 32-1

Immunologic Classification of Allergic Drug Reactions

Type	Type of Immune Response	Pathophysiology	Clinical Symptoms	Typical Chronology of the Reaction
I	IgE	Mast cell and basophil degranulation	Anaphylactic shock Angioedema Urticaria Bronchospasm	Within 1–6 hours after the last intake of the drug
II	IgG and complement	IgG and complement-dependent cytotoxicity	Cytopenia	5–15 days after the start of the eliciting drug
III	IgM or IgG and complement or FcR	Deposition of immune complexes	Serum sickness Urticaria Vasculitis	7–8 days for serum sickness/urticaria 7–21 days after the start of the eliciting drug for vasculitis
IVa	Th1 (IFN-γ)	Monocytic inflammation	Eczema	1–21 days after the start of the eliciting drug
IVb	Th2 (IL-4 and IL-5)	Eosinophilic inflammation	Maculopapular exanthema, DRESS	1 to several days after the start of the eliciting drug for MPE 2–6 weeks after the start of the eliciting drug for DRESS
IVc	Cytotoxic T-cells (perforin, granzyme B FasL)	Keratinocyte death mediated by CD4 or CD8	Maculopapular exanthema, pustular exanthema, Stevens-Johnson Syndrome (SJS)/TEN	1–2 days after the start of the eliciting drug for fixed drug eruption 4–28 days after the start of the eliciting drug for SJS/TEN
IVd	T-cells (IL-8/CXCL8)	Neutrophilic inflammation	Acute generalized exanthematous pustulosis	Typically 1–2 days after the start of the eliciting drug (but could be longer)

PATHOGENESIS

DHRs cannot be attributed to a single immunopathologic mechanism. Traditionally, an allergic drug reaction was thought to occur in two phases, initial sensitization and subsequent elicitation.[6] Most drugs are small molecules (<1,000 Da) and are unable to stimulate an immune response. Sensitization occurs as a result of covalent binding of a drug or a metabolite to a carrier protein in a process referred to as haptenation.[1,7] This drug–protein (or drug metabolite–protein) complex is sufficiently large to induce the production of drug-specific T- or B-lymphocytes and IgM, IgG, and IgE. On reexposure to the drug, the patient is likely to present with allergic symptoms.[7] Allergic reactions to β-lactam antibiotics occur by this mechanism. This theory, however, cannot explain several allergic phenomena. For instance, some chemically inert drugs (i.e., drugs that cannot form stable covalent bonds and do not have reactive metabolites) can still elicit an allergic response. Lidocaine and mepivacaine are examples. Furthermore, some patients have a strong allergic reaction to a drug on initial exposure, and some allergic reactions rapidly occur after drug exposure, a time period shorter than expected for the development of new antibodies. To account for some of these observations, other models for explaining allergic reactions have been proposed. The direct pharmacologic interaction concept offers one explanation for these observations. This model suggests that some drugs are able to bind directly to T-cell receptors in a reversible, non-covalent manner.[8] The drug–T-cell receptor complex interacts with Major Histocompatibility Complex (MHC) molecules, leading to activation and expansion of T-cells that are directed against the drug.[9]

Recent studies have demonstrated an additional mechanism whereby abacavir and carbamazepine can alter the shape and chemistry of the antigen-binding cleft via non-covalent interactions in patents with specific HLA variants. These alterations cause endogenous peptide to be viewed as foreign and lead to the activation of T-cells. This process is referred to as the altered repertoire model.[10,11] Undoubtedly, the processes involved in allergic reactions are complex and might include some combination of each theory. The three models of hapten sensitization, direct pharmacologic interaction, and altered repertoire are not mutually exclusive. Interested readers are referred to more in-depth reviews.[12]

PREDISPOSING FACTORS

Factors known to affect the incidence of allergic reactions can be categorized as being drug-related or patient-related.[3] Patients with histories of allergic rhinitis, asthma, or atopic dermatitis who experience a systemic drug reaction tend to react more severely than others.[3,13,14]

Age and Sex

Children are less likely to become sensitized than adults, presumably because children typically have less cumulative drug exposure.[1,13] More female than male patients experience allergic reactions (up to 2.3:1), although this may vary by type of reaction, drug, patient age, and setting.[3,14]

Genetic Factors

Familial occurrences of allergic reactions, although rare, have been reported.[15] A patient's ability to metabolize a drug is influenced by his or her genetic makeup and may affect the incidence of DHRs.[12,16–18] In humans the major histocompatibility complex is encoded by a group of genes on chromosome 6 called the human leucocyte antigen (HLA) system. Variations in HLA is probably the most important genetic determinant of drug allergies.[12]

Genetic differences in drug metabolizing enzymes can explain the predisposition to drug allergy and hypersensitivity of some individuals.[12] Examples of the phenotypic expression of these polymorphisms include poor metabolizers (who possess nonfunctional alleles and have reduced metabolic activity) and ultrarapid metabolizers (who have multiple copies of functional genes and have enhanced metabolic activity).[18,19]

Slow acetylators are at risk for sulfonamide hypersensitivity and are also more likely to develop antinuclear antibodies (ANA) and symptoms of systemic lupus erythematosus (SLE) when treated with procainamide or hydralazine.[20] Anticonvulsant hypersensitivity syndrome, characterized by fever, generalized rash, lymphadenopathy, and internal organ involvement, is most associated with aromatic anticonvulsants (e.g., phenytoin, phenobarbital, and carbamazepine). Oxidation of these compounds by cytochrome P-450 enzymes results in arene oxides that are antigenic. Patients with a heritable deficiency in epoxide hydrolase cannot clear the formed antigen and are at increased risk of a drug sensitivity syndrome also known as DRESS (drug rash with eosinophilia and systemic symptoms).[21] A polymorphism might also be responsible for a serum sickness–like reaction to cefaclor.[19]

While polymorphism in drug metabolizing enzymes is responsible for some allergic reactions, variation in MHC appears to be more important.[12,16] HLA polymorphisms mostly map to the antigen-binding cleft, thereby diversifying the repertoire of peptide antigens selected by different HLA allotypes. Several important DHRs reactions are associated with specific HLA alleles.[12] For example, HLA-B*1502 is associated with increased risk (OR 17.6) of SJS with Carbamazepine (CBZ), phenytoin, and lamotrigine.[16] HLA-B*1502 occurs in 10% to 15% of individuals from southern China, Thailand, Malaysia, Indonesia, the Philippines, and Taiwan and has a prevalence rate of 2% to 4%, or higher, in other southern Asian groups, including Indians. It is uncommon in Japan and Korea (<1%) and in European Caucasians (0%–0.1%).[17]

The potentially life-threatening hypersensitivity syndrome seen with abacavir is strongly associated with the HLA-B*5701 haplotype.[12,22–25] HLA-B*5701 in patients predicted abacavir hypersensitivity 100% of the time, and its absence had a 97% negative predictive value.[25] This haplotype appears more commonly in white patients than in other ethnic groups and explains the predisposition of white patients to this severe reaction. Genetic screening of patients for this haplotype before initiating abacavir therapy has significantly reduced the occurrence of hypersensitivity reactions.[25] In the future, it is hoped that screening tests for HLA haplotypes associated with a variety of allergic reactions will become widely available.

A more comprehensive and up-to-date listing of alleles associated with immunologically mediated adverse drug reactions can be found at https://www.pharmgkb.org/.

Associated Illness

Although genes clearly play a role in hypersensitivity reactions, environmental factors (e.g., concomitant illness) also are implicated. For example, the incidence of maculopapular rash with ampicillin therapy is significantly higher in patients with Epstein–Barr virus infections (e.g., infectious mononucleosis), lymphocytic leukemia, or gout.[26] Infection with herpes virus or Epstein–Barr virus has also been linked to DRESS syndrome,[26] and the occurrence of reactions to trimethoprim–sulfamethoxazole in patients who are HIV-positive is about 10-fold higher than in the HIV-negative population.[22] Liver or kidney disease may alter the metabolism or elimination of reactive drug metabolites, increasing the risk of an allergic response.

Previous Drug Administration

A history of an allergic reaction to a drug being considered for treatment, or one that is immunochemically similar, is the most reliable risk factor for development of a subsequent allergic reaction.[1,26] A commonly encountered example is the patient with a history of a severe allergic reaction to penicillin, in whom all structurally related penicillin compounds should be avoided, and in whom the possibility of a hypersensitivity reaction should be considered when using other β-lactam antibiotics.[1,26]

Drug-Related Factors

The dose, frequency of exposure, and route of administration can influence the incidence of drug allergy. For example, penicillin-induced hemolytic anemia requires high and sustained drug concentrations.[27] In β-lactam antibiotic IgE sensitivity, frequent intermittent courses, rather than continuous therapy, are more likely to result in drug sensitization.[21] The route of administration is important in terms of the risk of both sensitization and allergic reaction in a previously sensitized person. Topical administration carries the greatest risk of sensitization, followed by subcutaneous, intramuscular (IM), and oral routes. The intravenous (IV) route is the least sensitizing route of administration.[28] However, in a patient who is already sensitized to a specific medication, the risk of an allergic reaction to that medication is greatest when it is given IV and least when given orally. This is thought to be a function of the rate of drug delivery.[28] Multiple drug therapy is associated with a greater risk of allergic reactions. This may be related to increased demands on metabolic pathways from multiple drugs, leading to the accumulation of reactive metabolites.[28]

Drugs as Allergens and Immunologic Classification

Although there are proposed changes to the nomenclature and classification of drug allergies,[29] the Gel and Coombs classification is the most common. In this system, allergic drug reactions can be classified into one of four types (Table 32-1).[1]

TYPE I: IMMEDIATE HYPERSENSITIVITY REACTIONS

Type I reactions are typically mediated by the immune globulin IgE. Initial exposure to an antigen results in production of specific IgE antibodies that are expressed on the surface of mast cells in the tissue and basophils in the blood. On reexposure, the antigen cross-links with two or more surface-bound IgE antibodies causing the release of several chemical mediators including histamine, tryptase, leukotrienes, prostaglandins, and cyotkines.[28]

A period of several weeks is required after initial exposure and sensitization before a type I reaction can be elicited; once sensitized, however, a type I response can be elicited within minutes as a result of existing antibodies. In addition, a type I reaction can occur on reexposure to small amounts of drug administered by any route.[28,30] Immune-mediated anaphylaxis is the classic example of a type I reaction. Reactions that clinically resemble anaphylaxis, but do not involve immunologic mediators (antibodies), are termed anaphylactoid or pseudoallergic reactions (see Case 32-6, Question 1).

TYPE II: CYTOTOXIC REACTIONS

Cytotoxic reactions involve the interaction of IgG or IgM and can occur by three different mechanisms (Table 32-1). Common clinical

---

manifestations of cytotoxic reactions include hemolytic anemia, thrombocytopenia, and granulocytopenia. Penicillin-induced hemolytic anemia is the best-known example of a cytotoxic drug reaction. This reaction typically appears after 7 days of high-dose therapy.[27]

TYPE III: IMMUNE COMPLEX–MEDIATED REACTIONS

Immune complex–mediated reactions result from the formation of drug–antibody complexes in serum, which often deposit in blood vessel walls, resulting in activation of complement and endothelial cell injury.[30] Also referred to as serum sickness, these reactions typically manifest as fever, urticaria, arthralgia, and lymphadenopathy 7 to 21 days after exposure.[26,30]

TYPE IV: CELL-MEDIATED (DELAYED) REACTIONS

In cell-mediated (delayed) reactions, an antigen binds with sensitized T-cells. Contact dermatitis is the most common manifestation of cell-mediated reactions, although systemic reactions can occur. The variety of clinical manifestations of delayed hypersensitivity has been attributed to distinct patterns of cytokine release and effector-cell recruitment, based on the type of T-cells stimulated. Each pattern of cytokine release recruits specific effector cells, such as macrophages, neutrophils, or other T-cells, and is responsible for the unique clinical manifestations of the reaction. Based on this understanding, type IV reactions have been further subclassified as type IVa, type IVb, type IVc, and type IVd, corresponding to four unique patterns of T-cell and effector-cell involvement.[31]

An understanding of the immunologic mechanism can be helpful in the diagnosis and treatment of an allergic reaction; however, the exact immunologic mechanism is unknown for many allergic reactions to drugs.[26] In addition, patients often present with several symptoms characteristic of more than one of the reactions described herein. The use of many drugs concurrently also makes it difficult to identify the drug responsible for the reaction. Therefore, a careful drug history and diagnostic tests are often necessary for an appropriate diagnosis and treatment of a patient.

DIAGNOSIS

Distinctive Features of Allergic Reactions

The first step in the diagnosis of an allergic drug reaction is to recognize and differentiate it from other adverse drug reactions. This can be accomplished by having a good understanding of the distinctive features of allergic drug reactions (Table 32-2).[26]

CASE 32-1

QUESTION 1: J.A., a 73-year-old woman, is admitted with an infected decubitus ulcer. Cultures reveal Staphylococcus aureus, which is sensitive to oxacillin, cefazolin, and vancomycin. On questioning, J.A. reports having experienced a rash to penicillin in the past. Her current medications include oral docusate 100 mg twice daily, oral enalapril 5 mg every morning, oral prednisone 20 mg daily, and oral ibuprofen 800 mg 3 times daily. What information should be obtained to determine whether J.A.'s rash represents an allergic drug reaction?

The single most informative diagnostic procedure for allergic drug reactions is a detailed drug history (Table 32-3), which is helpful in obtaining the information necessary to determine whether a reaction represents a drug allergy and in identifying the culprit drug. In inquiring about prior allergic and medication encounters, it is important to document the drugs to which the patient has or has not previously reacted. This can alert the clinician about certain types of compounds to which the patient is likely to react. The acquired information allows the clinician to characterize the drug reaction and to appreciate how such a reaction might be manifested in the patient on exposure to the same, or an immunologically similar, compound in the future.

Table 32-2

Clinical Features of Allergic Drug Reactions

- Are unpredictable
- Occur only in susceptible individuals
- Have no correlation with known pharmacologic properties of the drug
- Require an induction period on primary exposure but not on readministration
- Can occur with doses far below therapeutic range
- Can affect most organs, but commonly involves the skin
- Most commonly manifests as an erythematous or maculopapular rash, but includes angioedema, serum sickness syndrome, anaphylaxis, and asthma
- Occur in a small proportion of the population (10%–15%)
- Disappear on cessation of therapy and reappear after readministration of a small dose of the suspected drug(s) of similar chemical structure
- Desensitization may be possible

Table 32-3

Detailed Drug History

- Name of the medication
- Route of administration
- Reason medication was prescribed
- Nature and severity of reaction
- Temporal relationships between drugs and reaction (dose, date initiated, duration, when during the course of treatment did the reaction occur)
- Prior allergy history
- When did the reaction occur (days to weeks vs. months to years)
- Similar reactions in family members
- Prior exposure to the same or structurally related medications
- Concurrent medications
- Management of the reaction (effect of drug discontinuation; therapies required to treat the reaction)
- Response to treatment
- Prior diagnostic testing or rechallenge
- Other medical problems (if any)

Source: Khan DA, Solensky R. Drug allergy. J Allergy Clin Immunol. 2010;125 (2 Suppl 2):S126; Celik G. Drug allergy. In: Adkinson NF, ed. Middleton's Allergy: Principles and Practice. 7th ed. St. Louis, MO: Mosby; 2008:1205.

The temporal relationship between drugs and reactions is often the strongest piece of evidence implicating an allergic reaction to a particular agent. Drugs that the patient has received for long continuous periods before the onset of a reaction are less likely to be implicated than drugs that have been recently initiated or restarted.[26] Equally important is to determine when an adverse reaction has occurred. Many compounds have been reformulated over the years, resulting in removal of sensitizing

---

impurities (e.g., penicillin and vancomycin). Therefore, it is possible that reexposure to the agent will not result in an adverse event. Inquiring about whether the patient has received the drug since the first episode by asking the patient about other brands or names of other drugs in the same class (e.g., amoxicillin and ampicillin) will assist in determining whether the patient is likely to react to the drug on reexposure. It is usually helpful to chart all the drugs the patient is currently taking, their dose, and start and stop dates of use. This can be compared with the onset and disappearance of the reaction.

CASE 32-1, QUESTION 2: On further questioning, J.A. reports having experienced an urticarial rash in the past when given ampicillin for a kidney infection approximately 2 years ago. The rash developed over her entire body less than a day after starting the antibiotic and disappeared 2 days after discontinuation. Her treatment course was completed with ciprofloxacin. She denies having had a viral infection at the time of the rash to ampicillin. She does not recall having experienced any adverse effects when she received penicillin before this reaction. No other recent changes in her treatment regimen were made before the occurrence of the rash. Why is it likely that J.A. is allergic to penicillin?

Several pieces of information in the drug history obtained from J.A. can be used to determine the likelihood of an allergic reaction to penicillin. J.A.'s rash appeared less than a day after initiation of ampicillin and other drugs had not been added; therefore, the rash probably was caused by ampicillin.

Another important method of identifying a potential drug-induced allergic reaction is to examine the patient's medication list to determine whether the patient is receiving an agent that commonly is implicated in causing the exhibited allergic manifestation. For example, amoxicillin and ampicillin are two of the top three drugs implicated in drug-induced rash.[27]

J.A. received penicillin previously without experiencing any adverse effects until an urticarial rash (a relatively common allergic manifestation) developed on subsequent exposure. This sequence of events follows the typical pattern of an allergic reaction. Allergic reactions commonly require an induction period to sensitize the person to the antigen; however, once sensitized, allergic symptoms typically occur immediately on reexposure.[26] Therefore, a prior exposure to the same or structurally related compounds needs to be documented.

Finally, it is important to evaluate other medical problems that can elicit or mimic a reaction resembling drug allergy (see the "Associated Illness" section). Rashes to ampicillin commonly occur in patients with concurrent Epstein–Barr virus infection.[32] J.A. denies having a viral infection at the time of her rash, thereby strengthening the case that the rash was likely a manifestation of an allergic reaction.

Skin Testing

CASE 32-1, QUESTION 3: Would skin testing for penicillin allergy be appropriate for J.A.?

Although J.A.'s medication history strongly suggests that she is allergic to penicillin, a skin test and a drug rechallenge would more firmly establish her drug allergy. Penicillin degrades to major determinants (95%) and minor determinants (5%). Penicilloyl, the primary metabolite of penicillin, is referred to as the major determinant. The other derivatives are referred to as minor determinants. Of these, the parent compound (penicillin), penicilloate, and penilloate are the minor determinants most associated with allergic reactions. The terms major determinant and minor determinant refer to the frequency of antibody formation to these antigenic penicillin metabolite–protein complexes. These terms do not describe the severity of the allergic reaction. Indeed, the major determinant is thought to be responsible for accelerated reactions, but not anaphylaxis. The minor determinants are responsible for anaphylaxis and immediate systemic reactions.

Skin testing with these determinants is used to identify which patients have IgE antibodies to penicillin and which do not. The skin-testing antigen for the major determinant of penicillin is commercially available as penicilloyl polylysine (PPL; Pre-Pen), which was recently reintroduced into the United States after several years of absence.[33] Skin testing using Pre-Pen is a safe and effective procedure (Table 32-4), with less than 1% of positive responders developing systemic reactions.[34] In those in whom a false-negative response occurred, reactions were mild after penicillin administration and, in most cases, did not require drug discontinuation.[26,34] Skin testing with PPL identifies 80% of patients allergic to penicillin. When PPL is supplemented with skin tests for the minor determinants of penicillin, 99.5% of penicillin-allergic patients can be identified.[26] Of the minor determinants, only penicillin G is available in the United States, although a minor determinant mixture is marketed in Europe and Australia.[35]

The negative predictive value of skin testing was demonstrated when 34 purportedly "penicillin-allergic patients" needed β-lactam antibiotics during hospitalization. Each subsequently tested negative to penicillin skin-testing and no allergic drug reactions occurred.[36]

Penicillin and its metabolites become antigenic when combined with proteins and can precipitate a hypersensitivity reaction in a patient on reexposure. In patients with a history of penicillin hypersensitivity, skin test reactivity is affected by the length of time since the allergic reaction and by the nature of the past reaction. Skin test positivity is greatest 6 to 12 months after a reaction and decreases with time. Skin test positivity in one study was found to be only 40% of patients with a history of anaphylaxis, 17% with urticaria, and 7% for maculopapular rashes.[37] Skin testing should not be performed in patients receiving antihistamines because they block the response to the antigen and can result in misinterpretation. In patients receiving antihistamines (i.e., H_1- or H_2-receptor antagonists) or when skin testing is not possible because of severe skin disease, in vitro assays to detect drug-specific IgE antibodies have been developed for the major and minor determinants of penicillin.

To determine whether skin testing is appropriate for J.A., the risks and benefits must be weighed. Because the time of the last reaction was approximately 2 years ago, J.A. may still retain some skin-test positivity if the previous reaction was truly an allergic response to ampicillin. Testing with PPL (major determinant) and penicillin G (minor determinant) could be useful in determining whether J.A. is likely to experience an urticarial or anaphylactic reaction to penicillin or its derivatives. That J.A. is currently receiving prednisone should not alter the interpretation of the skin test results because the corticosteroids minimally affect the IgE-mediated immediate hypersensitivity reactions. The risks of developing serious systemic reactions to penicillin skin testing are minimal.

The most practical approach to penicillin-allergic patients is simply to avoid the drug. In the unlikely situation in which treatment with a penicillin is essential, penicillin skin testing would be useful.

Cross-reactivity

CASE 32-1, QUESTION 4: J.A. received a scratch test with PPL, which was negative; however, an intradermal test was positive. What treatment options are available to J.A. for her infection?

Table 32-4

Penicillin Skin Testing Procedure

Agent	Procedure	Interpretation
Penicilloyl polylysine (Pre-Pen)	Puncture (scratch) test one drop of full-strength solution (6×10^{-5} mol/L)[a]	No wheal or erythema or wheal <5 mm in diameter after 15 minutes: proceed with intradermal test.
Major determinant		Wheal or erythema of 5 to 15 mm in diameter or more within 15 minutes: choose alternative agent, consider desensitization if no other alternatives exist.
PPL	Intradermal test: inject	Read at 20 minutes. Negative response: no increase in

	sufficient volume PPL to raise an intradermal bleb of 3 mm in diameter[a] Saline: negative control Histamine: positive control (optional; useful if it is suspected that patient may be anergic)	size of original bleb and no greater than reaction at control site. Positive response: itching and increase in size of original bleb to at least 5 mm and greater than saline control: choose alternative agent; consider desensitization if no other alternatives exist.
Penicillin G potassium (>1 week old) most important of the minor determinants	Scratch test one drop of 10,000 unit/mL solution	Same as scratch test with PPL (see above).
Penicillin G potassium	Intradermal test: 0.002 mL of 10,000 unit/mL solution	Same as intradermal test with PPL (see above).
	Serial testing with 10, 100, or 1,000 unit/mL solutions can be performed in those with strong history or serious reactions	

[a]PPL is administered initially as a scratch test. If no wheal or erythema develops, then intradermal testing is performed.

PPL, penicilloyl polylysine.

Source: Pre-Pen benzylpenicilloyl polylysine injection solution [package insert]. Round Rock, TX: ALK-Abelló, Inc; 2015. http://penallergytest.com/app/uploads/sites/2/Pre-Pen-Package-Insert.pdf Accessed July 20, 2017.

All penicillin derivatives should be avoided because J.A. had a positive skin-test reaction. Skin tests are not commercially available for cephalosporins and other β-lactam antibiotics. Although cephalosporin-skin testing (i.e., prick followed by intradermal instillation) has been proposed, no prospective studies have evaluated this approach and this practice is not without risk.[38,39] Therefore, clinicians must rely on cross-reactivity data to determine whether a non-penicillin β-lactam antibiotic (e.g., a cephalosporin) can be used in a penicillin-allergic patient.

Cross-reactivity (i.e., cross-antigenicity) between penicillin and cephalosporins has been reported in 5% to 15% of patients[34,37]; however, the true incidence of cross-reactivity is considerably less because these initial percentages were based on the recollection of patients of an allergic history rather than by objective skin tests.

The risk of a cephalosporin reaction in a patient with a penicillin allergy decreases with increasing cephalosporin generation: 5% to 16.5% for first-generation, 4% for second-generation, and 1% to 3% for third-generation and fourth-generation cephalosporins.[40] The risk of a serious allergic reaction with the use of an advanced-generation cephalosporin in a penicillin-allergic patient might be no greater than the risk of any alternative antibiotic.[41] The cross-reactivity between penicillins and cephalosporins formerly was attributed primarily to their common β-lactam chemical-ring structure; however, side-chain–specific reactions are now recognized to be responsible for a significant portion of allergic reactions within and between the penicillin and cephalosporins families.[38,41,42] In a study of 30 patients with immediate allergic reactions to cephalosporins, less than 20% reacted to penicillin determinants (i.e., skin test positivity, radioallergosorbent testing positivity, or both).[42] (Radioallergosorbent testing is a radioimmune test to detect IgE antibodies responsible for hypersensitivity.) This cross-reactivity between penicillin and cephalosporins is significantly less than earlier reports (up to 50%); however, the results of this study could be attributable to the greater use of third-generation, rather than the first-generation cephalosporins, which share more chemical structure similarities with the penicillins. Additional support for the importance of side-chain–specific reactions of β-lactams comes from observational data noting that 30% of patients with immediate reactions to penicillins were selective for amoxicillin.[43] In patients with allergy to amoxicillin, studies have found 2% to 38% cross-reactivity with the cephalosporin cefadroxil; both drugs share the same side chain.[30] Patients allergic to ampicillin may also have a greater risk of allergic reaction to cephalosporins that share the same side chain, such as cephalexin, cefaclor, cephradine, and loracarbef. Some patients also have multiple drug allergies and could manifest an allergic reaction to these drugs (and others that are not β-lactams) in a manner similar to their penicillin reaction.[37]

Cross-reactivity between penicillins and carbapenems (imipenem, meropenem, ertapenem, doripenem) and monobactams (e.g., aztreonam) has also been studied. One hundred twelve patients with a history of immediate reactions to a penicillin and a positive skin test to penicillin underwent skin testing with imipenem– cilastatin. One patient (0.9%) had a positive skin test. One hundred ten of the remaining 111 patients received gradually increasing IM doses of imipenem–cilastatin with no reactions observed.[44] Similarly, 108 children with a history of an immediate hypersensitivity reaction to a penicillin and a positive skin test underwent intradermal skin testing to meropenem. One child (0.9%) had a positive skin test. The remaining 107 subjects received increasing doses of IM meropenem with no reactions reported.[45] There also does not appear to be significant cross-reactivity between penicillins and the monobactam aztreonam.[46] Ceftazidime and aztreonam have an identical side-chain, however, and there is evidence of cross-reactivity between these two antibiotics.[47]

Although desensitization with an appropriate cephalosporin is a potential option for J.A. (see Case 32-9, Question 1), her infection is not life-threatening, and the organism is probably sensitive to another antimicrobial agents. In this case, it would be prudent to treat J.A. with a non–β-lactam antibiotic. If J.A.'s skin tests to cephalosporin were undertaken, and had been negative, she could receive a cephalosporin despite her positive history beginning with a cautiously administered small (i.e., “test”) initial dose.[37]

GENERALIZED REACTIONS

Drug allergies can be grouped into three categories: generalized reactions, organ-specific reactions, and pseudoallergic reactions. Generalized reactions involve multiple organ systems and variable clinical manifestations. Anaphylactic reactions, serum sickness reactions, drug-induced fever, hypersensitivity vasculitis, drug-induced vasculitis, and autoimmune drug reactions are the generalized drug reactions presented in this chapter.

Anaphylaxis

CASE 32-2

QUESTION 1: L.P., an 85-kg, 29-year-old man, presents to the emergency department with a chief complaint of a cat bite to the forearm 2 days prior. Physical examination reveals a man in moderate distress with multiple puncture wounds on the volar aspect of the right arm. The area surrounding the wounds is swollen, erythematous, and tender to the touch. L.P.’s history is notable for exercise-induced asthma, controlled with an albuterol metered-dose inhaler as needed, and a history of a laparoscopic appendectomy 3 years prior. He has no known allergies. The wound is cleansed with a germicidal soap and 3 g ampicillin/sulbactam is started intravenously. Three minutes after starting the ampicillin/sulbactam, L.P. notes tingling and pruritus of both his hands and feet, and appears flushed. One minute later he complains of light-headedness, difficulty breathing, and a lump in his throat. His vital signs at this time are blood pressure (BP) 100/60 mm Hg (normal, 125/85), heart rate 70 beats/minute (normal, 60), and respiratory rate 27 breaths/minute (normal, 12). Chest auscultation reveals restricted airflow and stridor. Anaphylaxis is the diagnosis and emergency treatment is started. What subjective and objective evidence support the diagnosis of anaphylaxis in L.P.?

Anaphylaxis is a serious allergic reaction that has a rapid onset and can cause death.[48] The diagnosis is considered probable if one of three clinical criteria are met[49]:

1. an acute onset of a reaction (minutes to hours) with involvement of the skin, mucosal tissue, or both, and at least one of the following:

respiratory compromise
reduced blood pressure or symptoms of end-organ dysfunction

2. two or more of the following that occur rapidly after exposure to a likely allergen for that patient:

involvement of the skin/mucosal tissue
respiratory compromise
reduced blood pressure or associated symptoms
persistent gastrointestinal symptoms

3. reduced blood pressure, after exposure to a known allergen

Anaphylaxis results from the rapid release of immunologic mediators from tissue mast cells and peripheral blood basophils.

The symptoms of anaphylaxis vary widely, depending on the route of exposure, rate of exposure, and dose of allergen.[30] Symptoms often begin within minutes of exposure, as in L.P., and most reactions occur within 1 hour. On rare occasions, anaphylaxis can appear several hours after exposure, and late phase or biphasic attacks have occurred 1 to 72 hours after the initial attack (most commonly within 8 hours). In general, the severity of the anaphylaxis is directly proportional to the speed of onset. L.P. displays symptoms in many of the organs commonly involved in anaphylaxis. Although almost any organ system can be affected, the cutaneous, gastrointestinal (GI), respiratory, and cardiovascular systems are involved most frequently, either singly or in combination.[30] These "shock organs" contain the largest number of mast cells and are the most highly affected.

L.P. exhibits erythema (flushed appearance) and complains of pruritus of his hands and feet, both common initial symptoms of anaphylaxis; the groin is also commonly affected. These symptoms can progress to urticaria and angioedema, especially of the palms, soles, periorbital tissue, and mucous membranes. L.P. describes the early manifestations of angioedema (laryngeal edema) with complaints of a lump in his throat (this may also be described as throat tightness or constriction by some patients).

The upper and lower respiratory tracts can also be involved during an anaphylactic event. L.P. exhibits stridor, indicating upper airway involvement. Hoarseness is another sign of upper respiratory tract involvement. In addition, L.P. is tachypneic with poor airflow, suggesting his lower airway also is affected. L.P. does not display wheezing or acute emphysema, which are further clues of lower airway involvement. Respiratory symptoms can lead to suffocation and death. In one autopsy series, laryngeal edema accounted for 25% of the fatalities and acute emphysema for another 25% of the deaths.[50] Cardiovascular symptoms also are ominous. Cardiovascular collapse and hypotensive shock (anaphylactic shock) are caused by peripheral vasodilation, enhanced vascular permeability, leakage of plasma, low cardiac output, and intravascular volume depletion. Thus, hypotension, as seen with L.P., is a common cardiac manifestation. Tachycardia also commonly occurs in patients with cardiac complications of anaphylaxis. L.P. does not show a significant increase in heart rate; however, he is taking the β-blocker atenolol. Other cardiac manifestations of anaphylaxis include a direct cardiodepressant effect and various electrocardiographic changes, including arrhythmias and ischemia.

Although not demonstrated by L.P., common GI manifestations such as abdominal cramping, diarrhea (which can be bloody), nausea, and vomiting are also manifested during an anaphylactic reaction.[30] In summary, L.P.'s rapid onset and progression of symptoms involving multiple organ systems (i.e., cutaneous, respiratory, and cardiovascular systems) are consistent with an anaphylactic reaction. L.P.'s anaphylaxis is a severe reaction given its speed of onset, the number of organ systems involved, and the degree of involvement. In particular, his respiratory and cardiovascular symptoms indicate a potentially life-threatening reaction.

CASE 32-2, QUESTION 2: What is the mechanism behind anaphylaxis and what is the likely cause of L.P.'s anaphylactic event?

Anaphylaxis occurs through one of three mechanisms.[30] In the first type of reaction, exposure to a foreign protein, either in its native state or as a hapten conjugated to a carrier protein, causes IgE-antibody formation. The IgE antibodies then bind to receptors on mast cells and basophils. On reexposure, the antigen stimulates cellular degranulation through both antigen-IgE antibody formation and cross-linking, which result in massive

---

release of preformed immunologic mediators from the mast cells and basophils. Histamine is the major mediator of anaphylaxis and the primary preformed cellular constituent. Histamine has multiple effects and is likely responsible for vasodilation, urticaria, angioedema, hypotension, vomiting, abdominal cramping, and changes in coronary flow.[30] Leukotrienes (e.g., leukotrienes C_4 and D, also known as slow-reacting substance of anaphylaxis), platelet activating factor, and prostaglandins are generated rapidly as a result of cellular degranulation, and other mediators of anaphylaxis (e.g., tryptase, chymase, carboxypeptidase A, tumor necrosis factor, and other cytokines and chemokines) are released as well.[30] Anaphylactic reactions to Hymenoptera venom (e.g., bee stings), insulin, streptokinase, penicillins, cephalosporins, local anesthetics, and sulfonamides occur through this IgE-mediated mechanism.

Anaphylaxis also can occur via the formation of immune complexes that activate the complement system and the subsequent formation of anaphylatoxins C3a, C4a, and C5a. Such anaphylatoxins can directly stimulate mast cell and basophil degranulation and mediator release. In 2008, cases resembling anaphylaxis in patients receiving heparin, particularly those also undergoing dialysis, were reported with almost 100 deaths occurring internationally. The culprit was found to be a contaminant (oversulfated chondroitin sulfate) that caused symptoms by this mechanism.[51,52]

The third mechanism by which substances, such as radiocontrast media and other hyperosmolar agents, can cause anaphylaxis is by the direct stimulation of mediator release (primarily histamine). The pathway by which this occurs is as yet unknown, but it is independent of IgE and complement.

Additionally, when no distinct mechanism can be associated with an anaphylactic event, the term idiopathic anaphylaxis is applied.[30]

Foods, insect stings, and drugs are the most common causes of anaphylaxis.[53] Antibiotics (particularly β-lactams and fluoroquinolones), nonsteroidal anti-inflammatory drugs (NSAIDs), neuromuscular blocking agents, radiocontrast media, chemotherapeutic agents, and monoclonal antibodies are the most common causes of drug-induced anaphylaxis. L.P.'s anaphylactic episode most likely is related to the first mechanism (i.e., IgE-antibody formation). L.P. is receiving a drug from a class of antibiotics well known to cause anaphylaxis. Specifically, L.P. may have received a prophylactic β-lactam antibiotic prior to his appendectomy, a standard of practice. Exposure to the antibiotic at that time stimulated IgE-antibody formation. After exposure to the β-lactam ampicillin/sulbactam in the emergency department, antibody–antigen complexes were formed, resulting in cellular degranulation and anaphylaxis. The temporal relationship of L.P.'s anaphylactic reaction to the administration of the antibiotic also strongly implicates ampicillin/sulbactam as the precipitating agent. Furthermore, L.P. was not exposed to agents known to cause anaphylaxis by one of the other known mechanisms. A review of L.P.'s surgical records is necessary to confirm his prior exposure to a sensitizing antibiotic.

CASE 32-2, QUESTION 3: Given L.P.'s signs and symptoms and the presumed cause of his anaphylactic reaction, how should he be treated?

Effective management of anaphylaxis requires quick recognition and aggressive therapeutic intervention because of the immediate life-threatening nature of the reaction, as illustrated by L.P. The severity of the anaphylactic reaction must be assessed quickly, the probable causative agent determined, the administration of the offending substance discontinued, and the absorption of the offending agent minimized if possible. Recent guidelines on the management of anaphylaxis list the following treatments in order of importance: epinephrine, patient position, oxygen, intravenous fluids, nebulized therapy, vasopressors, antihistamines, corticosteroids, and other agents.[49] All of these interventions must be undertaken promptly and the clinical status of the patient closely monitored. Vital signs, cardiac and pulmonary function, oxygenation, cardiac output, and tissue perfusion in particular must be immediately and continuously assessed.[30,49]

Although not definitively known to be the cause, the infusion of ampicillin/sulbactam should be stopped to prevent further exposure to the presumed precipitating agent. Additionally, the forearm wounds should be flushed with normal saline to remove any residual cleansing agent in the event that this is the cause of the reaction.

Pharmacologic treatment of anaphylaxis has traditionally involved several drugs and drug classes such as epinephrine, antihistamines, and corticosteroids aimed at reversing the clinical manifestations of anaphylaxis and interrupting the biological pathways involved. Recent literature reviews, however, failed to find well-designed and well-conducted randomized controlled trials to support the use of these drugs.[54–56] Recommendations for use are based on tradition, case reports, case series, and expert opinion.

L.P. is showing early signs of anaphylactic shock that must be managed immediately. Epinephrine is the drug of choice for the pharmacologic management of anaphylaxis and all national and international anaphylaxis guidelines recommend epinephrine as first-line treatment.[30,49,57] Studies have shown that failure to use epinephrine early in anaphylaxis is a risk factor for a poor outcome. Use of standard order sets and auto-injectors by emergency departments have been shown to increase epinephrine utilization for anaphylactic patients.[58]

The α-adrenergic effects of epinephrine increase systemic vascular resistance and increase blood pressure while decreasing mucosal edema and relieving upper airway obstruction, angioedema, and hives. These actions counter the vasodilating and hypotensive effects of histamine and the other mediators of anaphylaxis. In addition, the β-adrenergic effects of epinephrine promote bronchodilation and increase cardiac rate and contractility. Epinephrine also inhibits the release of mediators from basophils and mast cells.

The route of epinephrine administration is important. Most guidelines recommend IM epinephrine, 0.01 mg/kg of a 1 mg/mL (1:1,000) solution to a maximum dose of 0.5 mg in an adult or 0.3 mg in a child injected into the lateral aspect of the thigh every 5 to 10 minutes as needed.[58,59] Epinephrine doses should be expressed in mass concentration (e.g., 1 mg in 1 mL) instead of ratios such as 1:1,000, which have been confused with epinephrine concentrations used in cardiac arrest (1:10,000) and caused dosing errors.[57] Epinephrine is vasodilatory in skeletal muscle and because skeletal muscle is highly vascular absorption is rapid. While some guidelines propose the subcutaneous route for epinephrine administration, subcutaneous tissue is less vascular than skeletal muscle, thus there is less rapid absorption of epinephrine. Additionally, epinephrine causes vasoconstriction in subcutaneous tissue, therefore slowing its own absorption. Studies have shown that IM epinephrine injections into the thigh achieve higher blood concentrations more rapidly than do subcutaneous or IM injections into the arm in healthy subjects.[49] The rate and extent of absorption from IM and subcutaneous routes of epinephrine administration, however, have not been studied in patients experiencing anaphylaxis, and there is no evidence that epinephrine is ineffective when given IM or subcutaneously into the arm.[49] Epinephrine should be administered via the IV route in cases of anaphylaxis that have not responded to repeated doses of IM epinephrine and/or are progressing to shock, or in cases

---

where cardiorespiratory arrest appears imminent. Low cardiac output and intravascular volume depletion from shock decrease tissue perfusion and possibly the absorption of subcutaneous or IM injections. In animal studies, the benefits of intermittent IV boluses of epinephrine are short lived and a continuous infusion of epinephrine provides optimal results.[59] In L.P.'s case, an initial dose of 0.5 mg of 1 mg/1 mL epinephrine solution should be injected IM into his lateral thigh. This should be repeated every 5 minutes until symptoms improve.

Some evidence suggests poor outcomes in patients who are in an upright position during anaphylactic shock.[60] Placing L.P. in the Trendelenburg position (patient supine, inclined approximately 45 degrees with head at the lower end and legs at the upper end) might improve survival by enhancing perfusion to vital organs. After repositioning, oxygen should be started and normal saline infused at a rate sufficient to maintain perfusion to vital organs. Normal saline is the preferred crystalloid because it stays in the intravascular space longer than does dextrose and does not contain lactate (e.g., Lactated Ringer's solution), which could worsen metabolic acidosis. Circulating blood volume can decrease by as much as 35% in the first 10 minutes of anaphylactic shock because of vasodilation and fluid shifting from the intravascular to the extravascular space.[49] Therefore, vigorous fluid resuscitation might be necessary (e.g., 1–2 L of normal saline at a rate of 5–10 mL/kg in the first 5 minutes). Cerebral perfusion, as evidenced by adequate mentation, must always take precedence over BP readings when managing shock.

The effect of L.P.'s atenolol must also be considered. Patients taking a β-blocker, whether cardioselective or not cardioselective, could experience more severe episodes and more refractory episodes of anaphylaxis than patients not taking a β-blocker. This effect might be caused by a blunted response to epinephrine when given to treat anaphylaxis, resulting in refractory hypotension, bradycardia, and bronchospasm.[49] If L.P.'s BP and heart rate do not substantially improve shortly after initiating epinephrine, IV glucagon, which can stimulate heart rate and cardiac contractility independent of β-adrenergic blockade, should be given (Table 32-5). Airway protection is important because glucagon may cause emesis and there is a risk of aspiration, especially in drowsy or obtunded patients. Methylene blue, through its ability to reduce nitric oxide production (a known potent vasodilator) has been found to be effective in a small number of cases of anaphylaxis with refractory hypotension.[53,60] Other vasopressors such as dopamine (2–20 mcg/kg/minute) may be needed to maintain blood pressure if there is poor response to epinephrine and glucagon. Second-line treatment for anaphylaxis includes inhaled β-agonists, H_1 and H_2 antihistamines, and corticosteroids. In light of L.P.'s severe pulmonary reaction, he should receive a nebulized β-agonist (e.g., albuterol). If L.P.'s respiratory status fails to improve after pharmacologic intervention, intubation must be considered. Atenolol would not be expected to diminish the effect of albuterol because atenolol is a β_1 cardioselective β-blocker and the dose is low. Because histamine is the primary mediator of anaphylaxis, IV administration of an H_1 antihistamine such as diphenhydramine (50 mg every 6 hours until the reaction resolves) should be considered. Similarly, giving an H_2 antihistamine is a common practice. Both therapies present little acute risk to the patient, but as already noted, there are few data supporting their efficacy in treating anaphylaxis.[55]

Lastly, given the severity of his reaction and his pulmonary involvement, L.P. is a candidate for IV corticosteroids. Methylprednisolone, 125 mg every 6 hours for four doses, might be beneficial and is associated with minimal risk. Although commonly used, corticosteroids will not affect the acute course of the reaction because of their delayed onset of action (typically 4–6 hours after administration). Corticosteroids may impact a prolonged episode of anaphylaxis and could prevent or minimize the occurrence of a biphasic reaction, although this has not been proven in well-controlled trials. The effect of methylprednisolone on L.P.'s diabetes is not a factor because his condition is potentially life-threatening. Once stabilized, L.P. should be transferred to a critical care setting and monitored for a minimum of 24 hours because relapses of the anaphylactic reaction can occur.[30,49]

Serum Sickness

Serum sickness is a type III hypersensitivity reaction that results from the production of antibodies directed against heterologous protein or drug haptens with subsequent tissue deposition. The typical presentation of serum sickness includes fever, cutaneous eruptions (95%), lymphadenopathy, and joint symptoms (10%–50%).[61–64] Symptoms usually occur 1 to 2 weeks after exposure, but accelerated reactions can occur within 2 to 4 days in previously sensitized persons. Laboratory data are relatively nonspecific and are of little diagnostic value. For example, the erythrocyte sedimentation rate (ESR) and the serum concentration of circulating immune complexes usually are increased. Complements C3 and C4 are often low, whereas activation products C3a and C3a desarginine are elevated. Urinalysis might reveal proteinuria, hematuria, or an occasional cast.[61–64]

In most cases, serum sickness reactions are mild and self-limiting and resolve within a few days to weeks after withdrawal of the inciting agent. Antihistamines and aspirin can be used to relieve pruritus and arthralgias. In severe cases, corticosteroids might be used and can be tapered during 10 to 14 days.[61–64] At one time, heterologous serum (e.g., anti-thymocyte globulin made from rabbit or equine serum) was a leading cause of serum sickness. With the decline in use of these products, however, the most common causes of serum sickness today are penicillins and cephalosporins, although biological agents such as rituximab, infliximab, and natalizumab are increasingly associated with serum sickness.[65,66]

Drug Fever

CASE 32-3

QUESTION 1: M.M., a 57-year-old ill-appearing woman, is hospitalized with a 3-day history of difficulty breathing, left-sided chest pain on inspiration, fever, chills, and a productive cough. Her medical history is significant only for hypertension, well controlled on hydrochlorothiazide; she has no known drug allergies. M.M.'s physical findings on admission are temperature, 38°C; respirations, 20 breaths/minute; left-sided crackles heard on auscultation; oxygen saturation 85% on room air; and heart rate, 85 beats/minute. A chest radiograph reveals an infiltrate in her left lower lobe. Her white blood cell (WBC) count is 17,500 cells/μL with

the following differential:
Polymorphonuclear neutrophil leukocytes (PMN), 83% (normal, 45%–79%)
Bands, 12% (normal, 0%–5%)
Lymphocytes, 10% (normal, 16%–47%)
Basophils, 0% (normal, 0%–1%)
Eosinophils, 1% (normal, 1%–2%)

Community-acquired pneumonia is the diagnosis, and M.M. is empirically started on ceftriaxone 1 g IV daily, azithromycin 500 mg IV daily, and oxygen at 2 L/minute. Other medications include oral acetaminophen 325 mg every 4 to 6 hours as needed for temperature greater than 38°C, oral famotidine 20 mg BID, and oral hydrochlorothiazide 12.5 mg daily. Seventy-two hours later, M.M. is breathing without pain at a respiratory rate of 12 breaths/minute, her lungs are clear to auscultation, and her oxygen saturation is 98% on room air. She appears much better and offers no new complaints. Her temperature during the previous 48 hours has ranged from 38.6°C to 40°C, her pulse has ranged from 90 to 100 beats/minute, and her WBC count is 22,000 with the following differential: PMN, 89%; bands, 5%; lymphocytes, 12%; basophils, 0%; and eosinophils, 7%. Drug-induced fever is considered. What evidence supports this diagnosis? What is the mechanism for drug fever?

Table 32-5

Drug Therapy of Anaphylaxis

Drug	Indication	Adult Dosage	Complications
First-line Therapy			
Epinephrine	Hypotension, bronchospasm, laryngeal edema, urticaria, angioedema	001 mg/kg to a maximum of 0.5 mg of a 1 mg/1 mL solution IM every 5 minutes PRN; if progressing to cardiorespiratory arrest 1–3 mL of 1:10,000 (0.1–0.3 mg) IV for 3 minutes	Arrhythmias, hypertension, nervousness, tremor
		1 mL of 1 mg/mL (1:1,000) in 250 mL of normal saline IV at a rate of 4–10 mcg/minute	
		3–5 mL of 0.1 mg/mL (1:10,000) intratracheally every 10–20 minutes PRN	
Oxygen	Hypoxemia	40%–100%	None
Albuterol		0.5 mL of 0.5% solution in 2.5 mL of saline via nebulizer (i.e., 2.5 mg)	Arrhythmias, hypertension, nervousness, tremor
IV fluids	Hypotension	1 L of normal saline every 20–30 minutes PRN (rates as high as 1–2 mL/kg/minute may be necessary)	Pulmonary edema, CHF
Second-line Therapy			
Antihistamines	Hypotension, urticaria		
H_1 receptor antagonists[a]		Diphenhydramine 25–50 mg IV over 10–15 minutes Oral H_1 antagonists may be used in less severe cases.	Drowsiness, dry mouth, urinary retention; may obscure symptoms

			of continuing reaction
H_2 receptor antagonists[a]		Ranitidine 50 mg IV over 10–15 minutes or Famotidine 20 mg IV over 10–15 minutes	
Corticosteroids[a]	Bronchospasm; patients undergoing prolonged resuscitation or severe reaction	Hydrocortisone sodium succinate 100 mg IV every 3–6 hours for two to four doses or Methylprednisolone sodium succinate 40–125 mg IV every 6 hours for two to four doses	Hyperglycemia, fluid retention
Dopamine	Hypotension refractory to epinephrine	400 mg in 500 mL dextrose 5% at 2–20 mcg/kg/minute	Hypertension, tachycardia, palpitations, arrhythmias
Norepinephrine	Hypotension refractory to epinephrine	4 mg in 1 L dextrose 5% IV at a rate of 2–12 mcg/minute	Arrhythmias, hypertension, nervousness, tremor
Glucagon[b]	Refractory hypotension	1 mg IV for 5 minutes, followed by 5–15 mcg/minute in fusion	Nausea, vomiting

[a] Agents in these classes may be used as adjuncts to epinephrine. Controlled studies demonstrating a clear benefit in anaphylaxis are lacking. Do not delay the administration of epinephrine, supplemental oxygen, or IV fluid resuscitation by taking time to draw up and administer a second-line medication.

[b] Glucagon may be particularly useful in patients taking β-adrenergic blockers, because it can increase both cardiac rate and contractility regardless of β-adrenergic blockade. Choice of agent and starting doses should be patient-specific, weighing safety and efficacy.

IM, intramuscularly; IV, intravenously; PO, orally; PRN, as needed.

Drug fever is described as a febrile reaction to a drug without cutaneous symptoms and is estimated to occur in 3% to 5% of inpatients.[67] Drug fever can be challenging to identify and can be misinterpreted as a new infectious process or failure of an existing infection to respond to treatment. Such failure to recognize a drug fever can lead to prolonged hospitalization and unnecessary tests or medications.[68] Table 32-6 lists the characteristics of hypersensitivity drug-induced fever. The most important finding in the case of M.M. is her clinical improvement with respect to her pulmonary status despite a high-grade fever and persistent leukocytosis; she also appears healthier than expected if she had an untreated infection. Whereas a drop in her WBC count would be anticipated given her improving respiratory function, her WBC count remains elevated, consistent with hypersensitivity drug fever. Notably, her eosinophil count is increased, a frequent sign of hypersensitivity reactions. Despite her high-grade fever, she has a relative bradycardia; that is, her heart rate is not as elevated as expected if an infectious process were ongoing. Further, the timing of the symptoms favors a drug-induced fever (i.e., within days of starting a new medication). A definitive diagnosis can be made only by stopping the suspected offending agent, however, because fever generally resolves within 48 to 72 hours if a rash is not present. When a rash is present, on the other hand, the fever may persist for several days after stopping the implicated drug.

Table 32-6

Hypersensitivity Reactions to Drugs: Drug-Induced Fever

Frequency	True frequency is unknown because fever is a common manifestation and almost any drug can cause fever. Estimate is that 3%–5% of hospitalized patients experiencing adverse drug reaction suffer from drug fever alone or as part of multiple symptoms.
Clinical manifestations	Temperatures may be 38°C or higher and do not follow a consistent pattern. Although patients may have high fevers with shaking chills, patients generally have few symptoms or serious systemic illness. Skin rash (18%), eosinophilia (22%), chills (53%), headache (16%), myalgias (25%), and bradycardia (11%) can occur in patients with drug fever. Onset of fever after exposure to the offending agent is highly variable, ranging from an average of 6 days for antineoplastics to 45 days for cardiovascular agents. Occurrence of fever is independent of the dose of the offending agent.
Treatment	Although drug fever can be treated symptomatically (e.g., with antipyretics, cooling blankets), stopping the offending agent is the only therapy that will eliminate fevers. Patients generally defervesce within 48–72 hours of stopping the suspect drug.
Prognosis	Drug fever is usually benign, although one review[57] found a mean increased length of hospitalization of 9 days per episode of drug fever. Rechallenge with the offending drug usually results in rapid return of the fever. Although reexposure to the suspect drug was previously thought to be potentially hazardous, there is little risk of serious sequelae.

Source: Patel RA, Gallagher JC. Drug fever. Pharmacotherapy. 2010;30:57; Mackowiak PA, LeMaistre CF. Drug fever: a critical appraisal of conventional concepts. An analysis of 51 episodes in two Dallas hospitals and 97 episodes reported in the English literature. Ann Intern Med. 1987;106:728; Cunha BA, Shea KW. Fever in the intensive care unit. Infect Dis Clin North Am. 1996;10:185.

Drug fever can be caused by various mechanisms, although it is ascribed most commonly to a hypersensitivity reaction. Other mechanisms include the pharmacologic action of the drug (e.g., cell destruction from antineoplastic agents releases endogenous pyrogens); altered thermoregulatory function (e.g., increased metabolic rate from thyroid hormone); decreased sweating from drugs with anticholinergic properties (e.g., atropine, tricyclic antidepressants, and phenothiazines); drug-administration-related fever (e.g., amphotericin B and bleomycin); and idiosyncratic reactions (e.g., neuroleptic malignant syndrome from haloperidol, malignant hyperthermia from inhaled anesthetics).[67]

CASE 32-3, QUESTION 2: What agent is the most likely cause of drug fever in M.M.?

Most of the information available on drug fever is based on case reports or small case series and reviews of the literature.[68,69] Unfortunately, the literature is inconsistent with regard to the frequency of drug fever (e.g., very common, common, uncommon) and such descriptions are not supported by good clinical data.

Nevertheless, some drugs are more commonly associated with drug fever than others. These include anti-infectives as a class (especially β-lactam antibiotics), antiepileptics, and antineoplastics. Drug fever has also been reported frequently with amphotericin B, azathioprine, hydroxyurea, methyldopa, procainamide, quinidine, and quinine.[68–70]

In M.M.'s case, ceftriaxone or azithromycin is the most likely cause of her ongoing fever, given the timing of the reaction relative to beginning the antibiotics and the frequency of febrile reactions attributed to them, especially to β-lactam antibiotics. Febrile reactions have not been associated with acetaminophen, and famotidine is rarely a cause of fever without other symptoms of an allergic reaction. Although diuretics such as hydrochlorothiazide can cause fever, M.M. was taking this medication before admission without any ill effects, making this drug an unlikely culprit.

CASE 32-3, QUESTION 3: How should M.M.'s drug fever be treated? Can M.M. receive cephalosporins in the future?

Because M.M. has responded clinically, her antibiotics should be discontinued and her fever curve, WBC count, heart rate, and respiratory status followed. An oral antibiotic from another drug class (e.g., a fluoroquinolone) should be started to complete a 7-day to 10-day antibiotic course of therapy. Acetaminophen and other antipyretics should be avoided unless M.M. becomes uncomfortable from the fever because they can mask the response to the discontinuation of her antibiotics.

As with any hypersensitivity reaction, rechallenge with the offending drug can cause a similar, or sometimes greater, response. In M.M.'s case, reexposure to ceftriaxone (or another β-lactam antibiotic) or a macrolide might cause a febrile reaction. It is unclear, however, how large the risk of reexposure truly is. Although drug fever sometimes precedes more serious hypersensitivity reactions, evidence suggests there may be little risk to reexposure. Should M.M. require ceftriaxone (or another β-lactam or macrolide antibiotic) in the future, it would be prudent to administer the drug in a setting where M.M. can be monitored, at least initially, to ensure prompt treatment if an immediate hypersensitivity reaction develops.

Hypersensitivity Vasculitis

CASE 32-4

QUESTION 1: M.G., a 26-year-old woman with cystic fibrosis, is admitted for treatment of pneumonia. Sputum cultures obtained before admission reveal Alcaligenes xylosoxidans sensitive only to minocycline and chloramphenicol. M.G. is initiated on appropriate doses of these two antibiotics for a 2-week course. On day 8 of therapy, M.G. begins to complain of a rash on her legs. Physical examination reveals palpable purpura and a maculopapular rash on both lower extremities. Laboratory data reveal an elevated ESR and leukocytosis. What is the likely cause of M.G.'s rash and laboratory abnormalities?

M.G.'s presentation is suggestive of a diagnosis of hypersensitivity vasculitis.

Hypersensitivity vasculitis, also called cutaneous leukocytoclastic angiitis, is characterized by inflammation of the small blood vessel walls. These reactions occur when immune complex deposition within the small veins and arterioles activates complement, causing the release of chemotactic factors. These factors attract polymorphonuclear cells that cause vessel damage.[71–74]

Drug-induced Vasculitis

Approximately 10% of cases of cutaneous vasculitis are believed to be drug-related.[73] Approximately 100 drugs have been identified as causing vasculitis, including β-lactams, fluoroquinolones, NSAIDs, antiepileptics, and tumor necrosis factor blockers.[72–75] Interested readers are referred to more in-depth reviews.[74–76] The diagnosis of hypersensitivity vasculitis is based on five clinical criteria (Table 32-7), three of which must be present.[76] M.G. meets three of the five criteria, including age greater than 16 years, palpable purpura, and a maculopapular rash. In addition, minocycline, a medication that she was taking at the onset of the rash, has been associated with serum sickness and vasculitic-type reactions. Onset of symptoms typically occurs 7 to 10 days after initiation of drug therapy but can occur sooner on reexposure. Purpuric papules and macular eruptions, the most commonly observed findings, are usually symmetric and occur on the extremities (Table 32-8).[71] Hypersensitivity vasculitis can involve multiple organ systems. Renal damage, ranging from microscopic hematuria to nephrotic syndrome and acute renal failure, is common in patients with disseminated disease.[76] An enlarged liver with elevated enzymes is indicative of hepatocellular involvement. Although the lungs and ears can be involved as well, clinical manifestations are usually mild.[71] Arthralgia is also commonly observed. Laboratory examinations usually show nonspecific abnormalities of inflammation such as an elevated ESR and leukocytosis. In patients with cystic fibrosis experiencing acute pneumonia, these laboratory abnormalities could already be present and, therefore, will not be helpful in establishing the diagnosis of hypersensitivity vasculitis in M.G.

Table 32-7

Criteria for the Classification of Hypersensitivity Vasculitis

Development of symptoms after age 16
Medication at disease onset that may have been a precipitating factor
Slightly elevated purpuric (hemorrhagic) rash over one or more areas of the skin that does not blanch with pressure and is not related to thrombocytopenia
Maculopapular rash over one or more areas of the skin

Biopsy showing granulocytes around an arteriole or venule

The diagnosis of hypersensitivity vasculitis can be made if a patient exhibits at least three of these criteria.
Source: Calabrese LH et al. The American College of Rheumatology 1990 criteria for the classification of hypersensitivity vasculitis. Arthritis Rheum. 1990;33:1108.

Table 32-8

Hypersensitivity Reactions to Drugs: Clinical Manifestations of Drug-Induced Vasculitis

- Palpable purpura and maculopapular rash occurring symmetrically predominantly on the lower extremities
- Multiple organ systems may be involved:
  Renal: microscopic hematuria to nephrotic syndrome and acute renal failure
  Liver: enlarged liver, elevated enzymes
  Joints: arthritis
  Gastrointestinal: abdominal pain
- Laboratory data usually show nonspecific abnormalities of inflammation: elevated erythrocyte sedimentation rate and leukocytosis. Peripheral eosinophilia may be present and serum complement concentrations can be low. Histologic findings on biopsy reveal small blood vessels with leukocytoclastic or necrotizing vasculitis
- Onset typically 7–21 days after initiation of therapy

Source: Valeyrie-Allanore L et al. Drug-induced skin, nail and hair disorders. Drug Saf. 2007;30:1011.

CASE 32-4, QUESTION 2: What additional workup could be performed to confirm the diagnosis of drug-induced vasculitis in M.G.?

In addition to the previous workup, other laboratory and diagnostic procedures might demonstrate peripheral eosinophilia and low serum complement concentrations. A biopsy, which typically reveals granulocytes in the wall of a venule or arteriole and eosinophils at any location, would provide more definitive information.

CASE 32-4, QUESTION 3: How should M.G.'s hypersensitivity vasculitis be treated?

The first step is to discontinue the minocycline therapy. Drug-induced vasculitic reactions typically resolve on their own without additional interventions. If the reaction is severe, corticosteroids can be used.

Autoimmune Drug Reactions

CASE 32-5

QUESTION 1: R.F., a 24-year-old white male medical student, has been treated for 5 months with isoniazid because of a positive skin test for tuberculosis. He now is in the clinic with complaints of new-onset myalgias and arthralgias. Laboratory values obtained the morning of the visit are within normal limits except for a positive ANA titer and an elevated ESR. What is the likely cause of R.F.'s symptoms and laboratory abnormalities?

Some drugs can induce an autoimmune process characterized by the presence of autoantibodies and, in some instances, clinical features of an autoimmune disorder. A drug-induced syndrome resembling SLE is usually characterized by myalgias, arthralgias, positive ANA titers, and an elevated ESR (see Chapter 33, Systemic Lupus Erythematosus). All of these characteristics are manifested by R.F.

The first case of drug-induced lupus erythematosus (DILE) was recognized more than 60 years ago and was associated with sulfadiazine.[77] Subsequently, more than 80 drugs have been associated with DILE including isoniazid, chlorpromazine, quinidine, methyldopa, and minocycline; however, hydralazine and procainamide are the drugs most frequently associated with this syndrome.[78–80] As with idiopathic SLE, DILE can be separated into systemic, subacute cutaneous, and chronic cutaneous lupus. An exact incidence of DILE is difficult to ascertain because of changing patterns of drug use; however, it is estimated that 10% of SLE cases are drug-induced with 15,000 to 30,000 cases in the United States annually.[73]

CASE 32-5, QUESTION 2: How can the diagnosis of drug-induced lupus be differentiated from SLE in R.F.?

In contrast to idiopathic SLE, DILE is less likely to affect women and black patients.[79] On average, patients with DILE are twice as old as those with idiopathic SLE at the time of diagnosis. Individuals with a slow acetylator phenotype have a greater tendency to exhibit DILE; ANA after exposure to lupus-inducing drugs also

---

appear more rapidly.[81] In general, DILE is a milder disease than idiopathic SLE. Many patients with DILE, however, could fulfill the diagnostic criteria for SLE according to the American Rheumatism Association.[81–83] Arthralgias or myalgias accompanied by a positive ANA test can be the only clinical features for some patients with drug-induced lupus. Symptoms usually appear abruptly after several months to years of continuous therapy with the offending drug. Common complaints include fever, malaise, arthralgias, myalgias, pleurisy, and slight weight loss. Mild splenomegaly and lymphadenopathy have been reported occasionally. The skin is affected in about 25% of cases manifesting as photosensitivity on light exposed surfaces. The classic butterfly malar rash, discoid lesions, oral mucosal ulcers, Raynaud's phenomenon, and alopecia are unusual features in DILE in contrast to idiopathic SLE. In addition, the central nervous system and kidneys rarely are affected.[84] Laboratory abnormalities commonly include anemia and an elevated ESR. The evidence supporting a diagnosis of drug-induced lupus in R.F. includes white male predominance, abrupt onset and relatively mild symptomatology, and lack of the classic butterfly malar rash. More definitive tests include determining whether antibodies to single-stranded (indicative of drug-induced lupus) or double-stranded DNA (indicative of SLE) are present.

CASE 32-5, QUESTION 3: Should ANA have been monitored in an effort to detect drug-induced lupus at an earlier stage in this patient?

No. Although all patients with symptomatic drug-induced lupus test positive for ANA (which consist predominantly of single-stranded DNA and antihistone antibodies),[84] many patients taking lupus-inducing drugs become ANA positive without going on to experience lupus. In patients treated with procainamide, about 50% to 75% are positive for ANA after 12 months and 90% after 2 years or more of continuous therapy; only 10% to 20% of those patients actually experience lupus symptoms.[84–86] Similarly, up to 44% of patients are ANA positive after 3 years of hydralazine therapy, but DILE occurs in only 6.7% of patients after 3 years of treatment.[84] It is not necessary to discontinue therapy in asymptomatic patients with positive ANA because most of them will never exhibit clinical symptoms.[79]

CASE 32-5, QUESTION 4: How should R.F.'s drug-induced lupus be treated?

Musculoskeletal complaints can be treated with aspirin or an NSAID. More severe symptoms from pleuropulmonary or pericardial involvement may require the use of corticosteroids. Clinical features of DILE usually subside and disappear in days to weeks with discontinuation of the offending drug. Occasionally, these symptoms linger or recur over a course of several months before eventually disappearing. Serologic tests tend to resolve more slowly: ANA may persist for a year or longer.[79,87] Drug-induced lupus does not predispose patients to the subsequent development of idiopathic SLE.[88] In most instances, lupus-inducing drugs do not increase the risk of exacerbation of idiopathic SLE[89]; however, long-term treatment with isoniazid may worsen preexisting SLE.[90] Since R.F. has not yet completed his 6- to 9-month course of isoniazid therapy, an alternative agent should be prescribed for R.F. with appropriate monitoring (see Chapter 68, Tuberculosis).

ORGAN-SPECIFIC REACTIONS

The drug allergies in this chapter have been grouped into categories of generalized reactions, organ-specific reactions, and pseudoallergic reactions. The generalized reactions have been described first, the organ-specific hypersensitivity drug reactions affecting the blood, liver, lung, kidney, and skin are described next, and pseudoallergic reactions follow.

Blood: Immune Cytopenias

Drug-induced immune cytopenias (e.g., granulocytopenia, thrombocytopenia, and hemolytic anemia) result from type II–mediated allergic reactions (Table 32-1). A drug or drug metabolite binds to the surface of blood elements such as granulocytes, platelets, and red blood cells. IgG or IgM antibodies are formed and are directed against the drug or drug metabolite bound to the cell (i.e., hapten–cell reaction).[27] Typical symptoms associated with immune thrombocytopenia include chills, fever, petechiae, and mucous membrane bleeding. Granulocytopenia generally manifests with chills, fever, arthralgias, and a precipitous drop in the leukocyte count. Symptoms of hemolytic anemia can be subacute or acute and can be sufficiently severe to cause renal failure. The Coombs test is useful in identifying antibodies bound to red cells or circulating immune complexes directed against red cells. Antibiotics are the most commonly implicated class of drugs causing either neutropenia or hemolytic anemia.

Liver

Hypersensitivity reactions involving the liver can be classified as cholestatic or cytotoxic. Jaundice is usually the first sign of a cholestatic reaction, in addition to pruritus, pale stools, and dark urine. Cholestatic reactions usually are reversible on discontinuation of the offending agent. Cytotoxic reactions can involve hepatocellular necrosis or steatosis and can result in irreversible damage if not recognized early.

Lung

Pulmonary manifestations of drug hypersensitivity include asthma and infiltrative reactions. Asthma typically occurs as part of a generalized systemic reaction. Most reactions to drugs that involve asthma alone represent a pharmacologic side effect rather than a true allergic reaction.

Infiltrative reactions typically develop 2 to 10 days after exposure and manifest with cough, dyspnea, fever, chills, and malaise.[26] Infiltrative reactions vary in presentation from eosinophilic pneumonitis to acute pulmonary edema.

Kidney

The most common hypersensitivity reaction involving the kidney is interstitial nephritis. Typical findings include fever, rash, and eosinophilia. Methicillin is the drug most commonly associated with interstitial nephritis, although penicillins, sulfonamides, and cimetidine also have been implicated in renal hypersensitivity reactions.[27] (See Chapter 29, Acute Kidney Injury, for hypersensitivity reactions to specific drugs that adversely affect the kidney.)

Skin

Adverse reactions involving the skin are the most common clinical manifestation of drug allergy. Although several different types of cutaneous reactions are possible, most drug-induced skin eruptions can be classified as erythematous, morbilliform, or maculopapular in appearance.[27] In a surveillance study of drug-induced skin reactions, amoxicillin was the most common cause, followed by trimethoprim–sulfamethoxazole and ampicillin. Overall, allergic skin reactions were identified in 2% of hospitalized patients.[14]

Treatment of skin reactions includes discontinuation of the offending drug and general supportive care (see Chapter 39, Dermatotherapy and Drug-Induced Skin Disorders).

PSEUDOALLERGIC REACTIONS

CASE 32-6

QUESTION 1: C.C., a 37-year-old man with no known allergies, is hospitalized for treatment of methicillin-resistant S. aureus (MRSA) bacteremia associated with an infected central line. His medical history is significant for short-bowel syndrome requiring parenteral nutrition and one previous episode of MRSA line infection successfully treated with vancomycin. Similar to his last admission, vancomycin 750 mg IV for 60 minutes every 12 hours is begun. A trough level taken after the fifth dose, however, is 8 mg/L and the vancomycin dose is doubled to 1,500 mg IV every 12 hours, to be administered at the same rate. Fifteen minutes after the new dose of vancomycin is begun, C.C. experienced hypotension (100/70 mm Hg), tachycardia (85 beats/minute), generalized pruritus, and facial flushing. C.C. is diagnosed as having a pseudoallergic reaction to vancomycin. What subjective and objective data in C.C. are important in differentiating vancomycin pseudoallergic reaction from a true allergic reaction?

Pseudoallergic reactions (also called nonallergic hypersensitivity reactions) are drug reactions that exhibit clinical signs and symptoms of an allergic response but are not immunologically mediated.[91] They can manifest as relatively benign symptoms or as severe, life-threatening events indistinguishable from anaphylaxis (Table 32-9).[91] The latter response is described as an anaphylactoid reaction because it resembles true anaphylaxis, but it does not involve IgE-antibody formation.[27,91] The risk of such potentially severe reactions needs to be considered when prescribing agents known to be associated with anaphylactoid reactions. For example, the prophylactic use of antibiotics such as ciprofloxacin to prevent meningococcal infections during an outbreak was associated with a relatively high rate (1:1,000) of serious anaphylactoid reactions.[92] This would be of potentially greater importance in the setting of a mass prophylaxis program to combat exposure to anthrax. Unlike true allergic reactions, which require an induction period during which a patient becomes sensitized to an antigen, pseudoallergic reactions can occur on the first exposure to a drug. The development of pseudoallergic reactions can be dose related, manifesting when large doses of the drug are administered, when the dose is increased, or when the rate of IV administration is increased.[26]

C.C. has experienced a common pseudoallergic reaction to vancomycin, usually referred to as the "red man syndrome" or "red neck syndrome," which primarily occurs when large doses of vancomycin are administered rapidly. Differentiating between a true allergic response and a pseudoallergic response can be difficult because the signs and symptoms can be indistinguishable. For example, each of the symptoms experienced by C.C. (flushing, tachycardia, pruritus, and hypotension) is caused by histamine release and can occur during an anaphylactic episode (see Case 32-2, Question 2). To conclusively determine the cause of the reaction would require immunologic testing for antibodies to the suspect drug or agent, which is not always possible or practical. In this case, C.C. had uneventfully received vancomycin previously and has tolerated five doses during this hospitalization; therefore, it is unlikely that the reaction is immunologically mediated (i.e., a true allergic reaction). Furthermore, the reaction occurred after an increase in his vancomycin dose, which further supports the diagnosis of a pseudoallergic reaction.

CASE 32-6, QUESTION 2: Why did vancomycin cause a pseudoallergic reaction in C.C.?

Pseudoallergic reactions from vancomycin occur because of a drug-induced histamine release that occurs through an as yet unknown pathway. Direct drug-induced release of histamine does not involve complement activation or IgE-antibody formation. Several other drugs (e.g., deferoxamine, opiates, pentamidine, phytonadione protamine, radiocontrast media) are known to directly stimulate histamine release.[13,91]

Some drugs (e.g., radiocontrast media and protamine) cause pseudoallergic reactions via both complement activation and direct-histamine release mechanisms. Furthermore, some drugs (e.g., vancomycin, quaternary ammonium muscle relaxants, and ciprofloxacin) can cause both true allergic reactions and pseudoallergic reactions.[7]

Table 32-9

Hypersensitivity Reactions to Drugs: Pseudoallergic Reactions

Frequency	Highly variable, depending on the agent involved. For example, up to 30% of patients taking aspirin exhibit a cutaneous pseudoallergic response. On the other hand, pseudoallergic reactions to other agents, such as phytonadione and thiamine, are rare.
Clinical manifestations	Range from benign reactions (e.g., pruritus and flushing) to a life-threatening clinical syndrome indistinguishable from anaphylaxis. Commonly require a higher drug dose to elicit the response than a true IgE-mediated reaction. May arise less quickly (>15 minutes after exposure) than true allergic reaction.

Diagnostic workup	Skin tests and identification of specific antibodies are negative.
Treatment	Pseudoallergic reactions are treated the same as true allergic reactions (i.e., according to the clinical presentations of the patient). Thus, some reactions simply may require removal of the suspect agent, whereas some anaphylactoid reactions may require aggressive therapy (e.g., epinephrine, antihistamines, and corticosteroids).
Prognosis	As with true allergic reactions, patients who have experienced a pseudoallergic drug reaction may have a similar reaction on reexposure. The severity of response may lessen, however, with repeated administration. Furthermore, for some drugs, the frequency and severity of the reaction also may be influenced by the dose or rate of intravenous administration. Pretreatment regimens to reduce the frequency and the severity of responses have been developed for some drugs well known to cause pseudoallergic reactions (e.g., radiocontrast media).

CASE 32-6, QUESTION 3: How should C.C.’s pseudoallergic reaction be treated? Does treatment of pseudoallergic reactions differ from that of true allergic reactions?

The first step in treating C.C.’s reaction is to eliminate the underlying cause. Thus, his vancomycin infusion should be held until the reaction resolves. Because the reaction is histamine-mediated, administration of an antihistamine such as diphenhydramine 50 mg IV is warranted. Observation of his BP and heart rate is mandatory. Intravenous fluids should be administered if his BP continues to fall or fails to stabilize. Patients with allergic reactions should be treated based on their clinical signs and symptoms, regardless of the mechanism behind the reaction. Thus, for all intents and purposes, pseudoallergic reactions are treated in the same manner as true allergic reactions.

CASE 32-6, QUESTION 4: Can C.C. continue to receive vancomycin? How can future reactions be prevented?

It is not necessary to discontinue vancomycin therapy in C.C. This reaction can be prevented by administering smaller doses of the drug more frequently (e.g., 1,000 mg every 8 hours rather than 1,500 mg every 12 hours) or infusing the dose for a longer interval, typically 2 hours. Alternatively, pretreatment with an antihistamine 1 hour before vancomycin administration is effective. In addition, tachyphylaxis to vancomycin-induced red man syndrome is independent of pretreatment with antihistamine and is another characteristic that differentiates a pseudoallergic reaction from a true allergic reaction. Pretreatment regimens to prevent pseudoallergic reactions to various other drugs (e.g., radiocontrast media) are also well described and can be effective.

CASE 32-6, QUESTION 5: What other drugs are commonly associated with pseudoallergic reactions?

Many other agents have been associated with pseudoallergic reactions.[7] Some of the agents more commonly associated with pseudoallergic reactions are described next.

Aspirin/Nonsteroidal Anti-Inflammatory Drugs

After penicillins, aspirin is the drug most commonly reported as causing “allergic” reactions. Reactions to aspirin can be divided into three broad categories: respiratory reactions, cutaneous manifestations, and anaphylaxis. None of these reactions has been consistently associated with IgE.[26,93]

RESPIRATORY

The prevalence of bronchospasm with rhinoconjunctivitis is 0% to 28% in children with aspirin sensitivity. In adult asthmatics, the prevalence of aspirin sensitivity ranges from 5% to 20%. The prevalence of aspirin sensitivity during aspirin challenge in adult asthmatics with a history of aspirin-induced respiratory reaction ranges from 66% to 97%.[94] Symptoms usually occur within 30 minutes to 3 hours of ingestion. The triad seen in many sensitive patients is aspirin sensitivity, nasal polyps, and asthma. All potent inhibitors of cyclo-oxygenase can cause respiratory symptoms in aspirin-sensitive patients. Thus, patients who react to aspirin should be considered sensitive to NSAIDs, and vice versa. Weak cyclo-oxygenase inhibitors, such as acetaminophen, choline magnesium salicylate, salicylamide, salsalate, and sodium salicylate, are generally well tolerated in patients with aspirin sensitivity.[93]

CUTANEOUS

The prevalence of cutaneous reactions to aspirin depends on the type of reaction and the population studied. For example, urticaria-angioedema occurs in 0.5% of children, 3.8% of the general adult population, and in 21% to 30% of patients with a history of chronic urticaria. Disease activity at the time of aspirin challenge plays an important role in those with a history of chronic urticaria. In one study, 70% of patients whose urticaria was active at the time of challenge reacted to aspirin, compared with only 6.6% of patients whose urticaria was not active at the time of challenge. Furthermore, aspirin or NSAID may aggravate preexisting urticaria.[93–95] Other dermatologic reactions to aspirin occur with less frequency; for example, eczema, purpura, and erythema multiforme occur in 2.4%, 1.5%, and 1% of the population, respectively.

ANAPHYLAXIS

The true prevalence of aspirin-induced or NSAID-induced anaphylaxis is unknown, but it may range from 0.07% of the general population to 10% of patients with anaphylactic symptoms. Although IgE is not consistently associated with aspirin or NSAID-related reactions (including anaphylaxis), aspirin-induced or NSAID-induced anaphylaxis shares three characteristics with immune-mediated anaphylaxis that point to IgE as a cause. First, the reaction occurs after two or more exposures to the offending agent, suggesting that preformed IgE antibodies are responsible. Second, patients do not have underlying nasal polyposis, asthma, or urticaria. Third, the patient who reacts to aspirin or a single NSAID can tolerate a chemically unrelated NSAID, suggesting that a drug-specific IgE antibody has been formed.[93,96]

The NSAIDs that selectively inhibit cyclo-oxygenase-2 (COX-2) while sparing cyclo-oxygenase-1 (COX-1) include celecoxib, rofecoxib, and valdecoxib, among others. Celecoxib is the only COX-2 inhibitor currently marketed in the United States. Selective inhibition of COX-2 provides anti-inflammatory effects while minimizing the renal effects, GI toxicity, and antiplatelet effects seen with inhibition of COX-1. Aspirin and older NSAIDs are nonselective inhibitors of cyclo-oxygenase, inhibiting both COX-1 and COX-2. Anaphylactoid or hypersensitivity reactions have been reported with celecoxib, and it appears that the rate of hypersensitivity is comparable to that of traditional NSAIDs.[96] Notably, celecoxib prescribing information states that, as with any NSAID, use is contraindicated in patients who have experienced asthma, urticaria, or allergic-type reactions after taking aspirin or other NSAIDs. Several reports, however, describe successful administration of celecoxib and other COX-2 selective agents to patients with aspirin-sensitive asthma or a history of hypersensitivity reactions to traditional NSAIDs, and evidence suggests that inhibition of COX-1 rather than COX-2 is key to initiating these events.[97–100] Nevertheless, COX-2 selective agents can still elicit allergic responses by other means (e.g., IgE-mediated hypersensitivity). Thus, appropriate precautions and monitoring should be followed when initiating therapy in any patient with a history of allergic reactions to aspirin or other NSAIDs.

Angiotensin-Converting Enzyme Inhibitors and Angiotensin II–Receptor Blockers

CASE 32-7

QUESTION 1: K.J., a 48-year-old woman, seeks care at an urgent care center. She presents with impaired speech but is able to swallow; she has red and swollen lips and tongue, and puffy eyes. Her medical history includes hypertension, atrial fibrillation, and a new diagnosis of hypercholesterolemia (plasma cholesterol, 290 mg/dL). Although her BP had been well controlled on hydrochlorothiazide, her diuretic was discontinued about 3 weeks ago because of its effect on cholesterol, and enalapril 5 mg daily was started. K.J. also takes a multivitamin (one tablet each day) and warfarin (5 mg daily). Her physical examination shows BP, 130/87 mm Hg; heart rate, 70 beats/minute; lungs clear to auscultation and percussion; respirations, 12 breaths/minute; and skin without rash or urticaria. Her condition is attributed to angioedema induced by enalapril. What is angioedema, and what evidence supports this diagnosis? What is the mechanism behind angioedema?

Angioedema refers to a localized, transient swelling of the deep skin layers or the upper respiratory or gastrointestinal mucosa. Angioedema commonly manifests as localized erythematous edema, involving the tongue, lips, eyelids, and mucous membranes of the mouth, nose, and throat. However, in rare cases it can occur in the lower gastrointestinal tract. Angioedema can be caused by a variety of mechanisms involving complement, histamine, substance P, and bradykinin that can be hereditary, immunologically acquired, or pharmacologic. ACE inhibitors are the most common pharmacologic cause and have been associated with this adverse effect in about 0.1% to 0.7% of individuals treated with this drug class and account for up to 60% of cases of angioedema that present to emergency departments.[101] The reaction is not dose-related and occurs with all ACE inhibitors. ACE inhibition causes accumulation of excess bradykinin leading to capillary leakage. Bradykinin receptor B2 is a G-protein– coupled receptor found in blood vessels and encoded by the BDKRB2 gene in humans.[102]

K.J. presents with classic symptoms of angioedema and does not have symptoms of a true anaphylactic reaction, further strengthening the diagnosis of drug-induced angioedema. Symptoms of angioedema usually occur within the first week of starting therapy, although they can occur at any time, even years later. Thus, although angioedema developed 3 weeks after K.J. began enalapril, the temporal relationship is reasonable.

CASE 32-7, QUESTION 2: How should K.J. be treated? Would an angiotensin receptor blocker (ARB) be an appropriate substitute for her ACE inhibitor?

Although angioedema can be life-threatening, symptoms are usually mild and resolve within hours to days of stopping the offending drug. The most common life-threatening complication of angioedema is airway obstructions. More severe reactions affecting the upper airway must be treated emergently with appropriate measures to maintain airway patency. A small clinical trial of ACE-induced angioedema comparing treatment with corticosteroid and antihistamine (prednisolone 500 mg IV and clemastine 2 mg IV) to treatment with icatibant (30 mg subcutaneous injection) found that the time to initial relief and complete symptom resolution were significantly shorter with icatibant.[102] Additional trials are currently evaluating icatibant and hopefully will help define which patients will be most likely to benefit from this drug.

K.J. does not need to be hospitalized because her respirations are not compromised and she is not experiencing swallowing difficulty; however, she should be kept under observation at the urgent care center to ensure that her angioedema does not worsen. She can be treated with icatibant 30 mg subcutaneously or she can be observed and later sent home with instructions to seek emergent help if her breathing or swallowing becomes difficult. She should be instructed to discontinue her enalapril, follow up with her primary physician as soon as possible, and to request her community pharmacist to record this adverse reaction to enalapril into her drug profile at the pharmacy. Because angioedema occurs with all ACE inhibitors, K.J. must avoid all drugs in this class.

Angioedema with ARBs has also been reported,[103,104] although with less frequency than with ACE inhibitors. Many of the cases of ARB-induced angioedema involved patients with a history of ACE inhibitor–induced angioedema, but this is not consistently the case. Similar to the ACE inhibitors, angioedema to ARBs can occur at any time during treatment. In K.J.'s case, it would be best to avoid ARBs and ACE inhibitors. Instead, other antihypertensive agents that have little effect on cholesterol (e.g., calcium channel blockers) should be used.

Several other drugs have been associated with angioedema including aspirin, NSAIDs, antibiotics, radiocontrast media, and DPP-IV inhibitors (e.g., sitagliptin and saxagliptin).[101] The causes of angioedema with these drugs are less well understood but often occur after having ACE inhibitor–induced angioedema. These drug should be used with caution if KJ needs them in the future.

CASE 32-7, QUESTION 3: Are there other pseudoallergic reactions that occur with ACE inhibitors and ARBs?

Besides angioedema, cough is a pseudoallergic reaction caused by ACE inhibitors. It may occur in up to 39% of patients after 1 week to 6 months of therapy. Interestingly, it is more common in nonsmokers than in smokers; the incidence does not increase in patients with chronic airway disease or asthma. Cough is more common in women than men, is not dose-related, and, as with angioedema, occurs with all ACE inhibitors.[93,101,105] Several mechanisms appear to be responsible, including inhibition of the breakdown of bradykinin in the lung and increases in local mediators of inflammation such as prostaglandins and substance P. Although many approaches to the management of ACE-induced cough have been proposed,[105] angiotensin II–receptor blocking agents are the most promising alternative. Cough can occur with an ARB, but the frequency appears to be no more than that of placebo. Furthermore, most direct comparative trials between ARBs and ACE inhibitors demonstrate that the frequency of cough with ARBs is much lower than with ACE inhibitors.[105]

Radiocontrast Media

Radiocontrast media are widely used diagnostic agents, exceeding 75 million administrations annually.[106] Adverse reactions to radiocontrast media can be divided into immediate reactions (occurring within 1 hour of administration and include nausea, flushing, BP changes, bronchospasm, urticaria, angioedema, cardiac arrhythmias, convulsions, angina, and symptoms indistinguishable from true anaphylaxis) and non-immediate reactions (occurring 1 hour to 10 days after administration and include pruritus, maculopapular drug eruption, Stevens–Johnson syndrome, toxic epidermal necrolysis, and vasculitis). The cause of radiocontrast media reactions remains unknown, although histamine release, complement activation, and direct toxic effects on end organs might all play a role. Many of the adverse effects to radiocontrast media have historically been classified as pseudoallergic reactions because evidence did not support IgE mediation of these reactions. Recently, however, skin tests and laboratory evidence suggest an immunologic mechanism for radiocontrast media reactions.[106] The overall incidence of reaction to radiocontrast media is 0.7% to 13%, depending on the type of agent selected and whether the patient was pretreated before administration.[107] Conventional, ionic, high-osmolality contrast media produce reactions in 4% to 13% of recipients, whereas nonionic, low-osmolality agents produce fewer reactions (0.7%–3.1%). The mortality rate from

---

radiocontrast media is 1 to 2 cases per 100,000 procedures and is the same for ionic and non-ionic agents.[108]

Female sex, a history of asthma, and a history of reaction to contrast media are risk factors for reactions to radiocontrast media. Of these, a history of reaction is the most important; 21% to 60% of patients with a history of reaction to radiocontrast media will have a reaction on reexposure.[106] Several pretreatment regimens have been developed to minimize such occurrences. For example, 32 mg of oral methylprednisolone given 12 hours and 2 hours before a procedure involving a high-osmolality contrast medium can reduce the reaction rate by up to 45%.[107] Another pretreatment regimen uses oral prednisone 50 mg taken 13 hours, 7 hours, and 1 hour before the procedure, plus diphenhydramine 50 mg orally or intramuscularly 1 hour before the examination.[109] This latter regimen lowers the occurrence of pseudoallergic reactions to high-osmolality contrast media, even in high-risk patients (i.e., those with a history of severe anaphylactoid reactions). Note that a “seafood allergy” is not a risk factor for a reaction to radiocontrast media. Patients with food allergies do not require special pretreatment prior to procedures involving these agents.[108,110]

Narcotic Analgesics

Some opiates stimulate histamine release and, thereby, cause hypotension, tachycardia, facial flushing, increased sweating, or pruritus. Severe reactions are uncommon, however. In many cases, the opiate can be continued with administration of an antihistamine to treat the symptoms. If the reaction is significant, a non-narcotic alternate analgesic may be considered, or an opiate that does not cause histamine release can be substituted. Morphine and meperidine cause the greatest histamine release in both in vitro and in vivo studies. Codeine, hydromorphone, oxycodone, and butorphanol stimulate histamine release less commonly; and levorphanol, fentanyl, sufentanil, methadone, and oxymorphone have little to no effect on histamine levels. One of the more frequent reactions to epidurally or intrathecally administered opiates is pruritus, which does not appear to be mediated by histamine because narcotics that do not release histamine (e.g., fentanyl and sufentanil) still cause pruritus after spinal administration. Furthermore, the pruritus tends to develop several hours after the opiate has been administered, when serum levels of histamine are insignificant. The cause of pruritus from spinal opiates remains unclear. The reaction can be managed with antihistamines and low-dose naloxone or nalbuphine, while continuing with the spinal narcotic.[91]

Iron-dextran Injection

Parenteral iron is used in the treatment of iron deficiency when oral iron preparations cannot be used or are ineffective. This is most commonly seen in patients with anemia of chronic renal failure, particularly those treated with epoetin alfa or darbepoetin and undergoing hemodialysis (Chapter 28, Chronic Kidney Diseases). Iron preparations are associated with a wide spectrum of adverse events (e.g., chest pain, hypotension, hypertension, abdominal pain, nausea, vomiting, weakness, syncope, backache, arthralgias, myalgias, and hypersensitivity reactions). Hypersensitivity reactions can be manifested as urticaria, sweating, dyspnea, rash, fever, and as anaphylactoid reactions, which can be fatal. Consistent with a nonimmunologic mechanism, hypersensitivity reactions to iron are not dose-related and can occur with the first drug exposure.[111]

Iron preparations differ in regard to the salt or carbohydrate carrier used, molecular weight, and rate of hypersensitivity reactions. The first commonly used iron preparations were iron dextran, available as a high-molecular weight ferric oxyhydroxide and dextran solution (Dexferrum) and later as a low-molecular weight ferric hydroxide and dextran solution (INFeD). Adverse events occur more often with iron dextran preparations compared to non-dextran preparations and are highest with high-molecular weight iron dextran. Data reported to the FDA MedWatch program between 2001 and 2003 was used to determine the odds of adverse events between iron dextran products and two non-dextran products: sodium ferric gluconate and iron sucrose (also known as iron saccharate). Relative to the InFeD brand of iron dextran, patients receiving sodium ferric gluconate or iron sucrose were half as likely to experience an allergic reaction or any adverse reaction. An equal risk existed of experiencing an allergic reaction, or any adverse reaction, between sodium ferric gluconate and iron sucrose. Although sodium ferric gluconate and iron sucrose were safer than iron dextran, at least one death and five life-threatening reactions were reported with each of the four agents studied.[112] Ferumoxytol, an agent approved in 2009, was designed with a modified dextrose shell to reduce hypersensitivity reactions. In a comparison trial, there was a comparable safety profile but did include one anaphylactoid reaction but no deaths compared to iron sucrose.[113] Since approval, post-marketing FDA surveillance has demonstrated several reports of life-threatening and serious anaphylactoid reactions, including six deaths in a 10-month reporting period.[114] The prescribing information has been updated to include a black box warning for fatal and serious hypersensitivity reactions.[115] The newest iron product is ferric carboxymatltose complex, which releases iron from a carbohydrate polymer. Hypersensitivity reactions are expected to be lower as it does not contain an dextran or modified dextran component. In comparison to iron sucrose, no significant difference was found in the rate of hypersensitivity reactions or anaphylactoid reactions.[116,117] Although approval FDA was initially delayed because of a potential safety imbalance in the risk of death, subsequent pooled analysis has not validated the early findings, and the product was approved with only a warning for hypersensitivity reactions.[118,119]

All patients receiving iron dextran should receive a test dose to assess tolerance, the other iron preparations do not require a test dose per their prescribing information. It appears iron dextran–tolerant patients have little risk of experiencing a serious hypersensitivity or anaphylactoid reaction to sodium ferric gluconate or iron sucrose injection and can safely be given one of these products without a prior test dose. Similarly, patients who have never received any parenteral iron product can be administered sodium ferric gluconate or iron sucrose for injection without a prior test dose. Although studies support the safety of both sodium ferric gluconate and iron sucrose for injection in iron dextran–sensitive patients, such patients may be at increased risk for an anaphylactoid reaction or other serious hypersensitivity response, and test dosing in this population may be reasonable. Because of the risks associated with any of the parenteral iron products, close monitoring of the patient for at least 30 minutes after drug administration is necessary and the availability of resuscitative medication and personnel trained to evaluate and address anaphylaxis is prudent.

PREVENTION AND MANAGEMENT OF ALLERGIC REACTIONS

CASE 32-8

QUESTION 1: A.M., a 40-year-old woman, is hospitalized with a diagnosis of community-acquired pneumonia. Her medical history is noncontributory except for an uneventful course of ampicillin 6 months before admission for an ear infection. A.M. is empirically treated with cefuroxime 0.75 g IV every 8 hours. On day 2 of therapy, she develops a raised pruritic maculopapular rash on her back, abdomen, and upper extremities. Antacid, docusate sodium, albuterol by metered-dose inhaler, and multivitamins were initiated on the same day as the cefuroxime. How should A.M.'s allergic reaction be managed? How might her allergic reaction have been prevented?

When examining methods to prevent allergic reactions, three possibilities exist: (a) the patient has unknowingly been sensitized to a drug and experiences an allergic reaction on receiving the same or a similar drug again; (b) the patient has a history of an allergic reaction to a medication and mistakenly receives the same or a similar medication a second time and again develops an allergic reaction; and (c) the patient has a history of an allergic reaction to a medication and intentionally receives the same or similar medication again. As in the first situation, A.M.'s allergic reaction was unpredictable and, therefore, could not be prevented. To prevent future allergic reactions (i.e., the second situation), however, A.M.'s reaction should be well documented in the medical chart and pharmacy records. In addition, all patients should undergo a thorough drug history on hospitalization. Careful attention should be paid to differentiating drug intolerance (e.g., stomach upset) from true allergic reactions, and any allergic reactions elicited during an interview should be documented appropriately. Adequate communication of allergic reactions is the single most important method of preventing their occurrence.

As described earlier, the first step in managing an allergic reaction is to determine its cause. Given A.M.'s history of exposure to ampicillin, the timing of the reaction, and the low frequency of allergic reactions to her other medications, cefuroxime is the most likely candidate. Second, a decision regarding whether to stop the suspect drug should be made. This decision must be based on the severity of the reaction, the condition being treated, and the availability of suitable alternatives. When possible, an equally effective alternative drug should be substituted for the suspect agent, preferably one that is immunologically distinct to avoid cross-sensitivity (see Case 32-1, Question 4, for a discussion of cross-reactivity).[120] If a suitable alternative exists, the offending agent should be stopped and the reaction treated symptomatically if necessary. In the case of A.M., another antimicrobial (e.g., azithromycin, clarithromycin, trimethoprim–sulfamethoxazole) could be substituted for cefuroxime (Chapter 67, Respiratory Tract Infections) and her symptoms treated with an oral or parenteral antihistamine, as well as a low-potency topical corticosteroid if necessary.

Some cases are described by the third situation: a patient develops an allergic reaction (or has a well-documented history of drug allergy), and it is inappropriate or not possible to change to an alternative drug. If the sensitivity reaction is severe or life-threatening, desensitization should be considered (Case 32-9, Questions 1 and 2); premedication to prevent or minimize anaphylaxis is not effective.[29] If the reaction is minor (e.g., pruritus, rash, or gastrointestinal symptoms), premedication or management of the reaction with antiallergy medications (e.g., antihistamines) might be sufficient to allow completion of therapy. It is rare in such cases for the reaction to progress to more serious allergic symptoms such as anaphylaxis[120]; however, suppression of allergic symptoms should be undertaken cautiously because many immunologic reactions are not IgE mediated and may progress to serious reactions, despite treatment. In general, allergy suppression should be reserved for prevention of mild reactions that are known or strongly suspected to be IgE mediated.[7,120]

Desensitization

β-LACTAMS

CASE 32-9

QUESTION 1: K.A. is a 24-year-old primigravida in her eighth week of pregnancy with a history of angioedema secondary to penicillin. Her initial pregnancy screening revealed a positive Venereal Disease Research Laboratory reaction and a fluorescent treponemal antibody absorption titer of 1:64. K.A. denies a history of genital lesions, currently does not exhibit clinical signs or symptoms of syphilis, and denies previous treatment for syphilis. Based on the serologic evidence and her history, a diagnosis of early latent syphilis is made. Current treatment guidelines indicate that penicillin is the drug of choice for K.A. How can a possible reaction to penicillin be prevented in K.A.? Is premedication an alternative to preventing a reaction?

There are situations where a drug is medically necessary in a patient with a known or suspected allergy to the drug, alternative therapy is not available, and diagnostic testing does not exist. In such cases there are two options: induction of tolerance (also called desensitization) or a graded challenge. Desensitization is the process of administering gradually increasing doses of a drug in an effort to modify a patient's response to the drug so that it can then be safely administered.[108] This process has been used successfully to manage both immune-mediated and non–immune-mediated reactions. A graded challenge (also called incremental test dosing) is the process of careful administration of subtherapeutic doses of drug to determine if a patient is truly allergic. Although similar sounding, there are distinct differences between the two processes.[108] For example, unlike induction of tolerance, a graded challenge does not alter a patient's response to the drug. The initial drug doses used for inducing tolerance are sub-allergenic—as low as 1/10,000th of the final dose and the process can take several hours involving multiple doses, each slightly larger than the preceding dose. Starting doses for a graded challenge may be 1/100th of the final dose. The process generally involves fewer steps (as few as two) and can be typically accomplished more rapidly. If the graded challenge is completed and a therapeutic course of drug tolerated, a graded challenge is not required before future courses of the drug. Tolerance induction, on the other hand, is only maintained as long as the patient receives the suspect drug; any interruption of therapy will require the desensitization procedure to be repeated (see Case 32-9, Question 4).

The choice of drug desensitization or using a graded challenge depends on the likelihood of the patient having a true allergic reaction. A graded challenge may be appropriate in patients with a distant or unclear history of drug allergy; when the reaction seems minor or for which diagnostic testing is unavailable; or in cases where cross-reactivity is expected to be low. For example, a patient with a maculopapular rash to ceftriaxone may undergo a graded challenge to imipenem–cilastatin to assess tolerance. On the other hand, a patient with a well-described, severe IgE-mediated reaction to a drug may be better suited for tolerance induction. Importantly, graded challenge or tolerance induction should not be used in patients with a history of a severe non-IgE–mediated reaction such as hepatitis, hemolytic anemia, Stevens–Johnson syndrome, toxic epidermal necrolysis, or DRESS syndrome because of the risk of provoking a potentially life-threatening reaction.[108] Because K.A.'s reaction to penicillin may be potentially severe, premedication is not an option and desensitization to penicillin should be started. (See Chapter 72 Sexually Transmitted Diseases, for alternative therapy.)

CASE 32-9, QUESTION 2: How should K.A. be desensitized? Why should she be skin-tested before desensitization?

If possible before tolerance induction is begun, K.A. should be skin-tested (see Case 32-1, Questions 3 and 4) to confirm her penicillin allergy.[7,34,120] Patients who have a positive history of penicillin allergy, but whose skin tests are negative, can receive full therapeutic doses without desensitization with little risk of developing an allergic reaction. One author, for example, reported only one case of acute anaphylaxis in a skin test–negative patient given full therapeutic doses of penicillin in more than 1,500 skin tests; similar results have been reported by other investigators.[34,120] If skin testing cannot be performed or if K.A.'s skin test is positive, desensitization should be initiated. Acute oral desensitization to penicillin and other β-lactam antibiotics is well established.[121]

The oral route for β-lactam desensitization is preferred to the parenteral route because (a) exposure by the oral route is less likely to cause a systemic allergic reaction than parenteral exposure; (b) fatal anaphylaxis from oral β-lactam drug therapy is rare; (c) preformed polymers and conjugates of penicillin major and minor determinants to Penicillium proteins are not well absorbed after oral administration; (d) blood levels rise gradually, favoring univalent haptenation; and (e) fatal or life-endangering reactions have not occurred using current methods. In addition, oral desensitization can be accomplished over several hours.[7] If oral desensitization is not possible (e.g., if oral absorption is questionable), parenteral desensitization can be instituted. Although the subcutaneous and IM routes have been used, the IV route is quicker and allows better control over the rate and concentration of drug administered, and any untoward reaction can be detected promptly and treated rapidly.[7,122] Oral and parenteral desensitization methods have not been compared formally, however. Patients should not be premedicated before desensitization, because this may prevent detection of minor allergic responses that may precede more serious reactions. In addition, only experienced personnel should undertake desensitization in an appropriate setting where emergency resuscitative equipment is readily available because severe reactions can develop.[120] Thus, K.A. should undergo oral desensitization if her skin test is positive or if skin testing cannot be performed.

CASE 32-9, QUESTION 3: Is K.A. at risk for an allergic reaction during tolerance induction? If tolerance induction is successful, is she at risk for a reaction during full-dose penicillin therapy?

Acute β-lactam desensitization, regardless of the route or protocol chosen, is not without risk. Approximately 5% of patients experience mild cutaneous reactions during desensitization, although one study reported reactions in 20% of patients during oral desensitization.[7,123] If a reaction occurs during the desensitization procedure itself, the reaction may be treated and desensitization continued using lower doses, increased intervals between doses, or both, after the reaction has abated. Severe, fatal reactions during desensitization are rare.[122]

Uneventful β-lactam desensitization, however, does not guarantee patients will be without reaction during full-dose therapy. Approximately 25% to 30% of patients experience a mild reaction during therapy, and 5% experience more severe reactions, including drug-induced serum sickness, hemolytic anemia, or urticaria.[7] Reaction rates are no different in severely ill or pregnant patients compared with stable or nonpregnant patients, although those with cystic fibrosis may be more difficult to desensitize because of their high frequency of allergic reactions.[123,124] Despite the occurrence of reactions, full-dose therapy is possible for most tolerance-induction procedures, but suppression of the reaction (e.g., by diphenhydramine) may be required.[122] Tolerance induction is also dose-dependent as allergic symptoms can appear after a substantial increase in the dose after tolerance has been achieved.[7]

CASE 32-9, QUESTION 4: If K.A. requires penicillin at a later date, will she need to undergo desensitization again? What is chronic desensitization?

The desensitized state, once achieved, will persist for approximately 48 hours after the last full dose of antibiotic; after this time, drug sensitivity will return.[7,122] Thus, if K.A. requires future courses of penicillin, she will need to undergo desensitization once again. In some cases, those requiring long-term antibiotic therapy (e.g., for endocarditis), those who may require β-lactams at a future date (e.g., those with cystic fibrosis), or those who have occupational exposure to β-lactams, maintenance of the desensitized state can be considered. Chronic twice daily dosing of oral penicillin has safely resulted in “chronic desensitization.” Similar to acute desensitization, once therapy is interrupted, the allergic state returns.[7,27]

OTHER DRUGS

CASE 32-9, QUESTION 5: Have patients allergic to drugs besides β-lactams been desensitized successfully?

Although most experience with desensitization is with penicillin and other β-lactams, desensitization also has been accomplished with numerous other drugs, including allopurinol, vancomycin, antineoplastic agents, aspirin, and monoclonal antibodies.[66,123,124] Interestingly, not all of these cases represent IgE-mediated hypersensitivity reactions. For example, reactions to trimethoprim–sulfamethoxazole commonly occur in patients infected with HIV and may not be IgE mediated. Yet, given its role in treating and preventing Pneumocystis jiroveci pneumonia, successful desensitization to trimethoprim–sulfamethoxazole is commonly used.[124]

Systemic Lupus Erythematosus

Jerika T. Lam, Ann M. Lynch, and Mary A. Gutierrez

	CORE PRINCIPLES	CHAPTER CASES
1	Systemic lupus erythematosus (SLE) affects multiple organ systems with diagnoses based on clinical findings and objective criteria from the American College of Rheumatology (ACR) and Systemic Lupus Collaborating Clinics (SLICC) guidelines.	**Case 33-1 (Questions 1–4), Case 33-2 (Question 1), Table 33-2, Figure 33-1**
2	Management of SLE is complex and involves many specialists, including cardiologists and rheumatologists.	**Case 33-2 (Question 2)**
3	SLE treatment includes NSAIDs, corticosteroids, antimalarials, and immunosuppressants. The goals of SLE treatment should be considered when devising a treatment plan.	**Case 33-2 (Question 3), Case 33-3 (Questions 1–3, 5–6), Table 33-4**
4	Pregnancy considerations should be applied when selecting drug treatments for female patients with SLE.	**Case 33-3 (Questions 7–8)**
5	Hydroxychloroquine and cyclophosphamide could cause bothersome side effects. Monitoring parameters and management of hydroxychloroquine and cyclophosphamide side effects should be considered for SLE patients.	**Case 33-3 (Questions 4, 9–11), Table 33-4**
6	Belimumab is the first FDA-approved biologic treatment for SLE. The appropriate use and monitoring parameters should be considered to optimize its efficacy.	**Case 33-3 (Questions 12–17), Table 33-3, Table 33-4**
7	There are several drug–drug interactions pertaining to the treatments for SLE. Concomitant use of hydroxychloroquine and antacids could have a potential adverse effect.	**Case 33-4 (Questions 1, 2), Table 33-5**
8	Pharmacists can play an important role in the education of SLE, management of side effects, and monitoring of drug–drug interactions.	**Case 33-3 (Questions 2, 3, 5-9, 13), Case 33-4 (Questions 2–3), Table 33-4, Table 33-5, Table 33-6**

GENERAL PRINCIPLES

Systemic lupus erythematosus (SLE) is a chronic, autoimmune, inflammatory disease that affects multiple organ systems and primarily the connective tissue. Its presentation and disease progression are unpredictable and highly variable. This multi-organ disease is characterized by inflammation, autoantibody production, the deposition of complement-fixing immune complexes, and a clinical pattern alternating between disease flares and periods of remission.[1] In essence, the immune system attacks the body's own cells and tissue, resulting in a continuous inflammatory response and tissue and/or organ damage over time. While SLE can eventually affect any organ such as the lungs, nervous system, and cardiovascular, it mainly affects the skin, joints, and kidneys.[2] The 10-year survival rate is approximately 70% for patients with SLE.[3]

EPIDEMIOLOGY

SLE is more common among women than men (9:1) and generally occurs during childbearing age, with a peak age of onset between 15 and 45 years.[4,5] It is estimated that more than 16,000 new cases of SLE are reported annually in the U.S. with an average prevalence of 1.5 million Americans. Approximately 5 million people are afflicted with SLE globally.[6] Progression of SLE is usually slow. It typically begins as a benign disease without signs or symptoms (preclinical phase) to disease with mild-to-moderate symptoms with exacerbations or flares, resulting in the involvement of additional organs and sustained damage (clinical phase). Over time the disease will progress, continually relapsing and remitting until eventually reaching severe potentially fatal disease (comorbidities phase).[7] Isolated skin and musculoskeletal involvement are

---

associated with a milder course of disease and a higher survival rate over patients with renal and CNS involvement, which indicate more severe and progressive disease conditions.

PATHOPHYSIOLOGY

The specific cause of SLE is unknown. Many genetic, ethnic, environmental, and hormonal factors are identified as potential causative risk factors. As part of the genetic component involved in the development of SLE, there is no clear Mendelian pattern of inheritance. Siblings of patients with SLE have a risk disease of approximately 2%.[8] Identical twins have approximately 10-fold higher risk of SLE than dizygotic twins.[4] First degree relatives of patients with SLE have a 20-fold increased risk of developing SLE when compared to the healthy population.[9,10] The genetic risk for the disease is more likely associated with multiple genes than the deficiency of a single gene. Interestingly, genome-wide association studies have identified risk alleles shared between SLE and other autoimmune disorders such as rheumatoid arthritis, Graves' disease, multiple sclerosis, type 1 diabetes, and psoriasis.[11] SLE is more likely to develop in women of color, at a rate of 2 to 3 times higher than the rate for Caucasian women.[6] Furthermore, the symptoms are found to be more severe in African-American, Asian, Native American, and Hispanic women.[4,12] However, individuals of all ages, genders, and ancestral backgrounds are susceptible to having the disease.

The association of environmental factors to SLE remains unclear. Some of the exposure-related factors that have been implicated for causing SLE include smoking and ultraviolet radiation.[13] The proposed hypothesis behind cigarette smoke is that it is associated with the indirect generation of anti-double stranded-DNA (anti-dsDNA) and related to immunoregulatory effects of tobacco exposure. Thus, in genetically predisposed individuals with a smoking-related decreased ability to clear apoptotic cells, the excess levels of intracellular antigens may lead to the production of autoantibodies such as anti-dsDNA.[14]

UV Radiation

Exposure to sunlight may cause the occurrence of SLE and could exacerbate preexisting symptoms. Ultraviolet radiation has been implicated in cutaneous manifestations of SLE, such as macular, papular or bullous lesions, and erythema.[15] Systemic disease is rarely induced by ultraviolet radiation. Possible mechanisms that may link the pathogenesis of ultraviolet radiation and SLE include circulating antibodies to the Ro/Sjogren's syndrome type A (anti-Ro/SSA) and anti-La Sjogren's syndrome type B (anti-La/SSB) antigen particles that result in an autoimmune response.[2,15] Nevertheless, both anti-Ro/SSA and anti-La/SSB are more commonly associated with Sjogren's syndrome than with SLE.

Viral Infection

It has been considered for many years that viruses, particularly the herpes families and the Epstein–Barr virus (EBV) may trigger SLE via polyclonal immune activation, resulting in an activation of the autoimmune system.[16] EBV may reside in and interact with B cells, promoting interferon alpha production and contributing to the inflammatory process.

Female Hormones

The increased prevalence in the female gender proposes that hormones such as estrogen or progesterone may play a role in aggravating the disease. Both estrogen and progesterone levels are increased during pregnancy and at conception. These hormones can lead to an increase in mature, high-affinity autoreactive B cells, resulting in an autoimmune reaction.[17] Evidence that SLE worsens during pregnancy ironically does not contribute to this theory as levels of estrogen and progesterone are lower in second- and third-trimester pregnant patients with SLE compared to healthy pregnant patients.[17] Interestingly, hormone replacement therapy is linked to worsening SLE symptoms in postmenopausal women.[18] The X chromosome may also independently contribute to the incidence of SLE, where the combination of two X chromosomes increases the severity of SLE over an XY combination.[19] The gene CD40 is located on the X chromosome and has been known to contribute to the pathogenesis of the disease.[13]

Immunologic Abnormalities

SLE is a disease of an overall dysregulated, aberrant immune function, indicated by a large number of autoantibodies involved. Abnormalities of the immune system include immune complexes, T lymphocytes, cytokines, and antibodies.[13] Antigen receptor-mediated activation is changed in T and B cells for patients with SLE. B cells play a pivotal role in the disease. They produce autoantibodies, which amplify inflammation and mediate tissue damage. The autoantibodies are immunoglobulin G (IgG)-mediated, and T lymphocytes help stimulate B cells to produce antibodies. Moreover, B cells process and present antigen and autoantigen to T cells and contribute to disease manifestation.[20] The innate immune system (i.e., toll receptors, plasmacytoid dendritic cells, and interferon alpha) and adaptive immune network also contribute to the production of autoreactive B cells and autoantibodies.[21] Similarly, cellular debris from apoptosis further stimulate activation of the immune system. The decreased clearance of cellular debris may be related to low-complement levels, such as C1q, C2, and C4, which normally function to help phagocytes and macrophages eliminate apoptotic material and self-reactive B cells. As a result, deposits of immune complexes can lead to organ damage, systemic inflammation, and pain.[5,13]

CLASSIFICATION CRITERIA

In 1971, the Diagnostic and Therapeutic Criteria Committee of the American College of Rheumatology (ACR) developed a disease classification criteria system. As there is no single test to diagnose SLE, the classification criteria have been used for the diagnosis of SLE. The original classification was revised in 1982 and again in 1997 to include more organs than just cutaneous involvement (Table 33-1).[22] In 2012, the Systemic Lupus Collaborating Clinics (SLICC) revised and validated the ACR SLE classification criteria in order to improve its clinical relevance and incorporate updated information about immunology in SLE (Table 33-2).[23] Either classification system, ACR 1997 or SLICC 2012, can be used.

CLINICAL PRESENTATION

The clinical features of the disease are diverse and vary among patients. Signs and symptoms may be subtle early in the course of the disease; and the spectrum of mild to severe symptoms may fluctuate, with periods of remission, throughout the disease process.[24] Clinical patterns of the disease can be categorized as constitutional, musculoskeletal, and mucocutaneous.

Constitutional symptoms usually include fatigue, general malaise, fever, and weight loss. These may occur in the early stages of the disease. Fatigue is the most common complaint and can be a debilitating symptom early on.[25,26] Musculoskeletal symptoms include arthritis, arthralgia, and myalgia. Early in the course of the disease the symptoms may be confused with rheumatoid arthritis, especially with intermittent symmetric arthritic and joint pain. Arthritis associated with SLE is non-erosive and does not damage the joint even though it affects the joints of the hands, wrist, knees, and feet. Myopathy may also be present during periods of active disease, or secondary to treatment of hydroxychloroquine and corticosteroids.[27]

Table 33-1

American College of Rheumatology Revised Criteria for Classification of Systemic Lupus Erythematosus, 1982 with 1997 Updates[22,46]

Criterion	Definition
1. Malar rash	Fixed erythema, flat or raised, over the malar eminences, tending to spare the nasolabial folds
2. Discoid rash	Erythematous raised patches with adherent keratotic scaling and follicular plugging; atrophic scarring may occur in older lesions
3. Photosensitivity	Skin rash as a result of unusual reaction to sunlight, by patient history or physician observation
4. Oral ulcers	Oral or nasopharyngeal ulceration, usually painless, observed by physician
5. Arthritis, non-erosive	Involving two or more peripheral joints, characterized by tenderness, swelling,

	or effusion
6. Serositis	Pleuritis—convincing history of pleuritic pain or rubbing heard by a physician or evidence of pleural effusion Or Pericarditis—documented by electrocardiogram (ECG) or rub or evidence of pericardial effusion
7. Renal disorder	Persistent proteinuria >0.5 g/day or >3+ if quantitation not performed Or Cellular casts—may be red cell, hemoglobin, granular, tubular, or mixed
8. Neurologic disorder	Seizures—in the absence of offending drugs or known metabolic derangements (e.g., uremia, ketoacidosis, or electrolyte imbalance) Or Psychosis—in the absence of offending drugs or known metabolic derangements (e.g., uremia, ketoacidosis, or electrolyte imbalance)
9. Hematologic disorder	Hemolytic anemia—with reticulocytosis Or Leukopenia—<4,000/mm^3 on ≥2 occasions Or Lyphopenia—<1,500/mm^3 on ≥2 occasions Or Thrombocytopenia—<100,000/mm^3 in the absence of offending drugs
10. Immunologic disorder	Anti-DNA: antibody to native DNA in abnormal titer Or Anti-Sm: presence of antibody to Sm nuclear antigen Or Positive finding of antiphospholipid antibodies on ■ an abnormal serum level of IgG or IgM anticardiolipin antibodies, ■ a positive test result for lupus anticoagulant using a standard method, Or ■ a false-positive test result for at least 6 months confirmed by Treponema pallidum immobilization or fluorescent treponemal antibody absorption test
11. Positive antinuclear antibody	An abnormal titer of antinuclear antibody by immunofluorescence or an equivalent assay at any point in time and in the absence of drugs associated with drug-induced lupus syndrome

Anti-DNA, anti-deoxyribonucleic acid; Anti-Sm, anti-Smith antibodies; IgG and IgM, immunoglobulins G and M.

Mucocutaneous manifestations occur frequently in patients with SLE. The malar or butterfly rash across the face is one of the classic cutaneous signs; however, it may not be present in all patients with SLE. It is an erythematous skin rash distributing over the cheeks and the bridge of the nose but spares the nasolabial folds. It can persist for weeks and resolves without scarring. The malar rash should be differentiated from flushing, glucocorticoid-induced dermal atrophy, rosacea, seborrheic, atopic, and contact dermatitis.[2] Other cutaneous signs may include alopecia, discoid lesions, photosensitivity reactions, periungual erythema, nail fold infarcts, and splinter hemorrhages.[28,29] In comparison, mucosal symptoms can include vasculitis and painful, recurrent ulcers in the mouth, nose, and genital cavity.[27] Raynaud's phenomenon may also occur in patients with SLE. It is described as a vasospastic disorder of the extremities, commonly affecting the hands and is characterized by color changes as a result of decreased temperature or intense stress.[18] It can also lead to avascular bone necrosis, which is a major cause of disability in SLE patients.[2]

Additional clinical presentation of SLE may include the development of antiphospholipid antibodies (e.g., lupus anti-β2-glycoprotein, IgG and IgM anticardiolipin antibodies, and IgG and IgM anti-β2-glycoprotein I) in the blood and places patients with SLE at increased risk for developing blood clots.[30] Livedo reticularis is a common feature of antiphospholipid syndrome (APS), which will be further discussed in the hematologic section. Common symptoms of SLE are described in Figure 33-1. Other major organ systems may also be affected by SLE, including the nervous system, cardiovascular, pulmonary, gastrointestinal (GI), renal, and hematologic.

Table 33-2

Systemic Lupus International Collaborating Clinics Classification Criteria 2012 for Classifying Systemic Lupus Erythematosus[23]

A patient can be classified as having SLE if he/she	■ Satisfies 4 of the criteria listed in Table 33-1 including at least one clinical criterion and one immunologic criterion Or ■ Has biopsy-proven nephritis compatible with SLE and with antinuclear antibody (ANA) or anti-dsDNA antibodies
Clinical and Immunologic Criteria Used in the SLICC Classification Criteria[a]	
Clinical Criteria	
1. Acute cutaneous lupus (includes lupus malar rash; do not count if malar discoid) and the following:	■ Bullous lupus ■ Toxic epidermal necrolysis variant of SLE ■ Maculopapular lupus rash ■ Photosensitive lupus rash in the absence of dermatomyositis Or ■ Subacute cutaneous lupus ■ Nonindurated psoriaform and/or annular polycyclic lesions that resolve without scarring, although occasionally with post-inflammatory depigmentation or telangiectasia

2. Chronic cutaneous lupus includes the following:	■ Classic discoid rash
	  ■ Localized (above the neck)
	  ■ Generalized (above and below the neck)
	■ Hypertrophic (verrucous) lupus
	■ Lupus panniculitis (profundus)
	■ Mucosal lupus
	■ Lupus erythematosus tumidus

	■ Chilblains lupus ■ Discoid lupus/lichen planus overlap

3. Oral ulcers include the following: (in the absence of other causes, such as vasculitis, Behcet's disease, infection (herpes virus), inflammatory bowel disease, reactive arthritis, and acidic foods)	■ Palate
	  ■ Buccal
	  ■ Tongue
	Or
	■ Nasal ulcers

4. Non-scarring alopecia (in the absence of other causes such as alopecia areata, drugs, iron deficiency, and androgenic alopecia)	■ Diffuse thinning or hair fragility with visible broken hairs

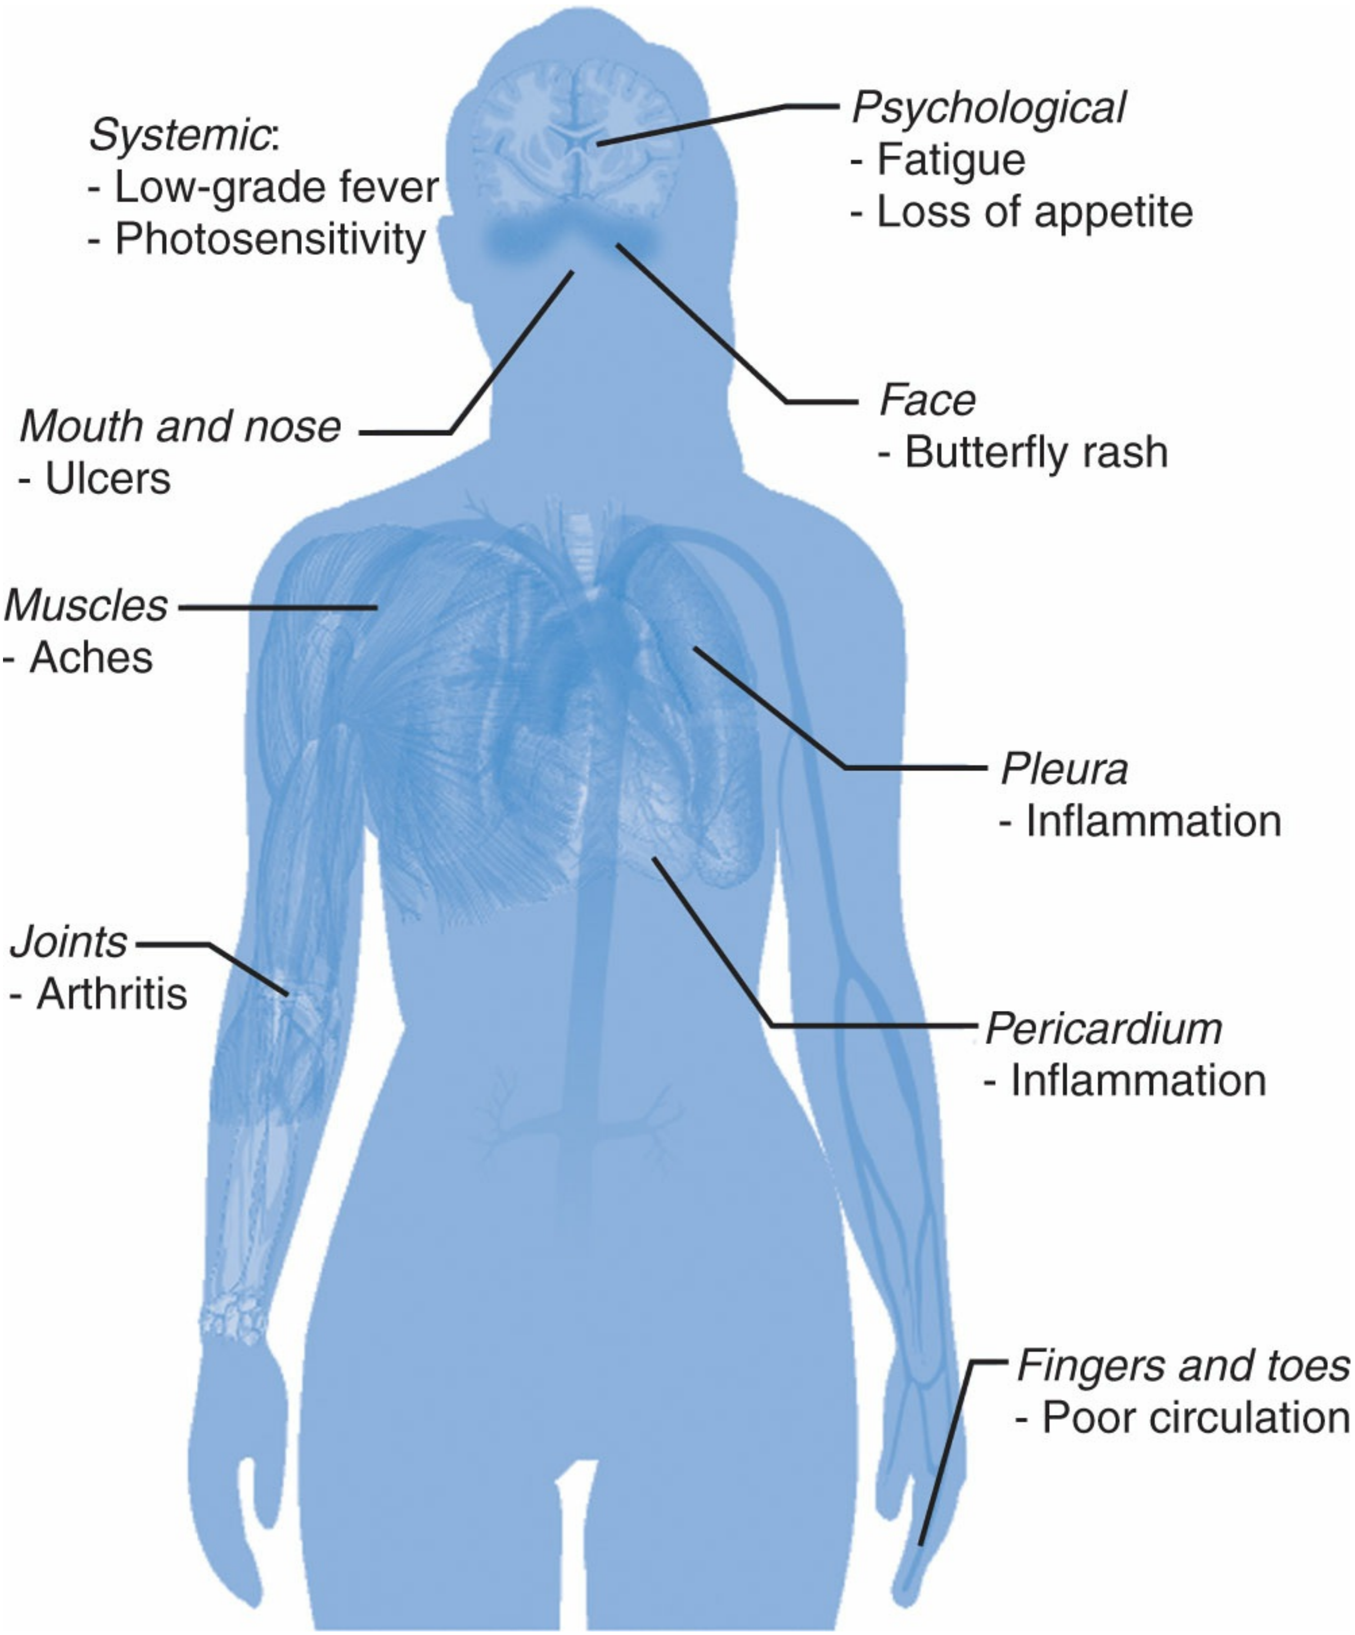
5. Synovitis	■ Involving two or more joints
	■ Characterized by
	  ■ Swelling or effusion
	Or
	  ■ Tenderness in two or more joints and at least 30 minutes of morning stiffness

6. Serositis	■ Typical pleurisy for more than 1 day Or ■ Pericardial effusion Or ■ Pericardial rub Or ■ Pericarditis by electrocardiography
7. Renal (in the absence of other causes, such as infection, uremia, and Dressler's pericarditis)	■ Urine protein-to-creatinine ratio (or 24-hour protein) representin 500 mg of protein/24 hour Or ■ Red blood cell casts
8. Neurologic	■ Seizures ■ Psychosis ■ Mononeuritis multiplex in the absence of other known causes, such as primary vasculitis ■ Myelitis ■ Peripheral or cranial neuropathy, in the absence of other known causes, such as primary vasculitis, infection, and diabetes mellitus ■ Acute confusional state, in the absence of other causes, includin toxic/metabolic, uremia, drugs
9. Hemolytic anemia	
10. Leukopenia	■ <4,000/mm^3 at least once (in the absence of other known cause such as Felty's syndrome, drugs, portal hypertension, and

	thrombotic thrombocytopenia purpura)
Immunologic Criteria	
1. ANA	■ Level above laboratory reference range
2. Anti-dsDNA	■ Antibody above laboratory reference range (or >2-fold the reference range if tested by ELISA)
3. Anti-Sm	■ Presence of antibody to Sm nuclear antigen
4. Antiphospholipid antibody positivity as determined by any of the following:	■ Positive test result for lupus anticoagulant ■ False-positive test for RPR ■ Medium- or high-titer anti-β2-glycoprotein antibody level (IgA, IgG, or IgM) ■ Positive test result for anti-β2-glycoprotein I (IgA, IgG, or IgM)
5. Low complement	■ Low C3 ■ Low C4 ■ Low CH50
6. Direct Coombs' test	■ In the absence of hemolytic anemia

[a] Criteria are cumulative and need not be present concurrently.

ELISA, enzyme-linked immunosorbent assay; Anti-dsDNA, anti-double stranded deoxyribonucleic acid; Anti-Sm, anti-Smith antibodies; RPR, rapid plasma reagin.



Systemic:
- Low-grade fever
- Photosensitivity
Psychological
- Fatigue
- Loss of appetite
Mouth and nose
- Ulcers
Face
- Butterfly rash
Muscles
- Aches
Pleura
- Inflammation
Joints
- Arthritis
Pericardium
- Inflammation
Fingers and toes
- Poor circulation

Figure 33-1 Common symptoms of systemic lupus erythematosus. (Source: Haggstrom, Mikael/Wikipedia Commons/Public Domain. http://www.commons.wikipedia.org/wiki/File:SymptomsofSLE.png. Accessed July 26, 2015.)

Nervous System

SLE affects both the central nervous system (CNS) and peripheral nervous system.

The CNS manifestations affect approximately two-thirds of patients with SLE.[30] Collectively, both have been described as neuropsychiatric syndromes. The pathology of the syndromes is not well understood. The syndromes may be ascribed to the autoimmune nature of SLE, where the immune anti-neuronal antibodies attack the neurons causing neuronal damage and leading to cognitive dysfunction, or the production of antiphospholipid antibodies that damage blood vessels and may cause clots in the brain.[28] Neuropsychiatric manifestations are nonspecific and variable. They may occur in less than 40% of patients with SLE, while the remaining events represent complications of the disease, therapies and therapy-related side effects, infections, and metabolic abnormalities.[31] Patients with SLE can present with higher rates of anxiety and depression. Depression is more common in those experiencing changes in appearance and limitations from complications and medication-related side effects.[32] Other manifestations include migraine headaches, memory loss, and seizures. Less common symptoms may also occur, such as psychosis, confusion, peripheral neuropathy, mood disorders, autonomic dysfunction, movement disorders, Guillain–Barre, and cerebrovascular disease.[27] Diagnosis and laboratory tests for neuropsychiatric events related to SLE continue to be challenging, as well as the therapies used for them.[33]

Cardiovascular

Patients with SLE are at increased risk of morbidity and mortality from cardiovascular disease, especially associated with atherosclerosis. Premature atherosclerosis is associated with longer lupus disease duration, more damage, and less aggressive immunosuppressive therapy.[34,35] They are at higher risk for myocardial infarction or stroke compared to the healthy population. In addition, pericarditis and pericardial effusion are the most common cardiac complications associated with SLE, occurring in approximately 45% of patients.[28,29,30,36] They range from mild-to-severe symptomatology. Patients may present with fever, dyspnea, tachycardia, and congestive heart failure. Other clinical features that may occur in more than 80% of patients with SLE include left ventricular dysfunction, segmental wall motion abnormalities, nonspecific ST-T wave changes, and decreased ejection fraction.[2] Valvular abnormalities can also be common and are linked to antiphospholipid antibodies. The most common

abnormality is diffuse thickening of the mitral and aortic valves followed by the presence or absence of nonbacterial vegetations (Libman–Sacks), valvular regurgitation, and stenosis.[2] Modifiable risk factors, in addition to comorbid disease screening, include reducing long-term steroid use as it is linked to the development of hypertension, smoking cessation, reducing homocysteine levels with folate supplementation, and preventing thrombosis with aspirin or anticoagulation in patients with APS.[27] These will help to reduce cardiovascular risk and control disease activity by reducing the inflammatory atherogenic effects.

CASE 33-1

QUESTION 1: T.C. is a 45-year-old Hispanic woman with hypertension, hypercholesterolemia, and an 18-year history of SLE. For the first 10 years after the diagnosis of SLE, she had frequent SLE flares and was treated with high-doses of prednisone. As a result, she developed steroid-induced diabetes and osteoporosis. Though her SLE has been relatively stable over the past 2 years, she has not been feeling well 1 month ago. T.C. denies symptoms consistent with her usual SLE flares, but she reports a sharp chest pain that worsens when lying down and improves when leaning forward, significant fatigue and shortness of breath with minor activity. She feels better after resting but has not returned to her previous energy level. She reports good adherence with her medications, which include the following:

Alendronate 70 mg weekly
Hydrochlorothiazide 25 mg every morning
Hydroxychloroquine 400 mg daily
Lisinopril 40 mg daily
Metformin 1,000 mg twice daily
Simvastatin 40 mg daily
Acetaminophen 650 mg prn pain

Findings from an examination of the patient are unremarkable, except for elevated blood pressure. Lupus anticoagulant antibodies are within normal limits. What is the most likely cause of T.C.'s complaints of fatigue and positional chest pain?

Patients with long-standing SLE are at increased risk for cardiovascular disease. Given that T.C.'s SLE is stable, cardiovascular disease is the most likely cause of her current symptoms.

CASE 33-1, QUESTION 2: What tests would best confirm your suspicion?

Electrocardiograms (EKGs), exercise stress tests, and echocardiograms. Cardiac stress test is also considered a best way to determine the presence and extent of her cardiovascular disease, especially for symptomatic patients.

CASE 33-1, QUESTION 3: Along with a referral to a cardiologist, which of the following treatments would you recommend that T.C. initiate at this time?

Aspirin is recommended because her most likely diagnosis is cardiovascular disease. She has no evidence of active SLE, so aspirin would be the most appropriate treatment at this time to prevent risk of thrombosis. Premature atherosclerosis with cardiovascular events tends to manifest as a late complication for patients with SLE. Oral anticoagulants may be considered for T.C. if she has developed antiphospholipid antibodies and APS.

CASE 33-1, QUESTION 4: Late in the disease course of SLE, what is the most common cause of high mortality rates?

Early in the disease course, mortality is primarily from inflammation affecting organ systems. Over time, mortality tends to be mostly from coronary artery disease and complications of chronic steroid therapy and immunosuppression. SLE disease could elevate the LDL and reduce the HDL levels in addition to treatment with systemic steroids that could worsen the cholesterol profile.

Pulmonary

Pulmonary involvement occurs in 30% of patients with SLE.[30] Pleuritis or pleural inflammation is the most common pulmonary manifestation of SLE. It is associated with chest pain, cough, and dyspnea. Pleural effusions are typical findings and are usually linked with antinuclear antibody (ANA)-positive exudates with low complement.[37] Alveolar hemorrhage is a common occurrence in patients with SLE, particularly in those with high titers of anti-dsDNA antibodies and active extrapulmonary disease.[30] Another respiratory complication is identified as the “shrinking lung syndrome,” which can occur in 25% of SLE patients.[2] It is characterized as progressive dyspnea (worse in the supine position) and weakness of the diaphragm and respiratory muscles. Acute lupus pneumonitis and pulmonary hypertension, although rare, could also develop as pulmonary complications.

Gastrointestinal

Nonspecific GI symptoms include abdominal pain, nausea, vomiting, diarrhea, and stomach upset. These are reported in 25% to 40% of patients with SLE, which could be disease-related or from medication side effects.[2] Other clinical manifestations include dyspepsia and peptic ulcers.

Renal

Up to 70% of all SLE patients will develop some form of renal complication, which is a poor prognostic indicator. Approximately 60% will have kidney involvement in the first 10 years of the disease.[18] Thirty-five percent of patients will develop nephrotic syndrome or lupus nephritis (LN) by the time of SLE diagnosis.[38] It is a serious kidney complication, which increases the risk of renal failure, cardiovascular disease, and mortality.[39] LN is caused by inflammation and deposits of immune complexes consisting of anti-dsDNA in the glomeruli. It includes proteinuria (>0.5 g/24 hours) and/or hematuria, described as active urinary sediment (>5 RBCs per high-power field, pyuria, or cell casts), in addition to a significant creatinine clearance reduction. For patients with inactive sediment and >500 mg/day of proteinuria, monitoring is recommended with urinalysis every 3 to 6 months for 3 years. More frequent monitoring, such as every 3 months, is preferred for patients with anti-dsDNA antibodies and/or hypocomplementemia.[40]

Aside from performing a urinalysis, a renal biopsy is required in all lupus patients with evidence of kidney involvement to determine the histologic subtype of LN and the extent of disease severity.[41,42] Pathology reports can elucidate the extent of inflammatory (reversible) and chronic (irreversible scarring) changes. LN can be an ongoing disease, with flares often requiring repeat biopsy and repeat treatment (refer to Chapter 28, Chronic Kidney Disease for Lupus Nephritis, Case 28-4).

Hematologic

Hematologic disorders can occur in patients with SLE. The most common hematologic manifestation is normochromic, normocytic anemia, which is often overlooked in young menstruating women. Iron deficiency may also develop. A common cause of anemia is suppressed erythropoiesis from chronic inflammation. Patients may have a positive Coombs test without apparent hemolysis.[42] Leukopenia and thrombocytopenia are also common manifestations

that can develop as part of the disease process, or may be a side effect of the pharmacologic treatment for SLE. Oftentimes, leukopenia consists of lymphopenia, not granulocytopenia.[43] Patients with SLE may also develop a thrombotic disorder known as APS. APS is characterized by the development of autoantibodies to phospholipids present in the serum. Antiphospholipid antibodies interfere with the coagulation system, particularly protein C and the function of endothelial cells.[13] APS features are described as venous or arterial thrombosis, miscarriages or spontaneous abortions, and thrombocytopenia from antiphospholipid antibodies.[27] The European League Against Rheumatism (EULAR) recommends low-dose aspirin in individuals with SLE and antiphospholipid antibodies as primary prevention of thrombosis and pregnancy loss.[7] Long-term use of oral anticoagulants is considered as secondary prevention of thrombosis in nonpregnant patients with SLE and thrombosis associated with APS. On the other hand, unfractionated or low-molecular-weight heparin and aspirin should be used in pregnant patients with SLE and APS.

Lymphadenopathy could be a common presentation in SLE, where it may occur in 15% to 26% in patients. Diffuse lymphadenopathy, however, is a very rare occurrence.[44,45] Lymph node biopsy may be considered to exclude alternative diagnoses.

DIAGNOSIS

Diagnosis is based on the presence of 4 or more of the 11 criteria, either serially or simultaneously, of the ACR classification. The revised criteria yields a sensitivity of 83% and a specificity of 96% for SLE diagnosis but are associated with several weaknesses.[22,46] For instance, many patients with biopsy-proven LN do not meet the criteria. Also, there have been numerous advances in imaging, serologic, and cerebrospinal fluid testing that resulted in an outdated CNS definition. The Systemic Lupus International Collaborative Clinics (SLICC) guidelines propose new criteria for the disease.[23] According to the SLICC criteria, a person is diagnosed with SLE when there is presence of at least 4 of the 11 criteria, of which one must be a clinical criterion and one an immunologic criterion.[23] Furthermore, the classification can also be made from a biopsy confirming LN and presence of antinuclear antibodies (ANA), or anti-dsDNA antibodies. Both anti-Smith (anti-Sm) and anti-dsDNA antibodies are highly specific for SLE, but anti-Sm antibodies lack sensitivity.[1] Anti-dsDNA and anti-Sm antibodies are found in approximately 70% and 30% of patients with SLE, respectively.[47] Other markers, such as the lupus anticoagulant and IgG and IgM antibodies to anticardiolipin are specific for APS. Their presence may increase the risk for thrombosis or miscarriages. When compared to the ACR classification, the SLICC criteria have higher sensitivity (97%) but not specificity (84%) (Table 33-2).[18]

The diagnostic workup can be challenging because of the complexity of the disease and overlapping features of many other autoimmune diseases, such as polymyositis, rheumatoid arthritis, and scleroderma. The workup includes an assessment of the clinical presentation, physical examination, diagnostic, and laboratory tests. Approximately 80% of patients have skin involvement manifesting as photosensitivity, alopecia, malar and discoid rash (thick, red, scaly patches on the skin), and ulcers in the oral and nasal cavities or in the vagina, all of which are part of the ACR criteria.[22]

CASE 33-2

QUESTION 1: P.J., a 26-year-old, obese (80 kg, 5-feet tall) African-American woman, presents to the emergency department complaining of chest pain. It is a sharp and substernal pain, but with a component that is diffuse and aggravated by deep aspiration. Two months ago she presented to the emergency department with a 6-week history of fatigue, low-grade fevers, hair loss, joint pain, and oral ulcers. Her laboratory tests showed a positive ANA test result. Blood cultures were negative for infection. The urinalysis was negative for blood, and the urine culture was negative for infection. A chest x-ray showed non-pulmonary infiltrates. Her symptoms improved after a 10-day tapering course of prednisone. Feeling better, P.J. decided not to follow-up with her physician's appointment last week. Today, the medical resident's examination reveals an ill-appearing woman, with a temperature of 100.5°F (38.06°C), oral ulcers, alopecia, and tachycardia with distant heart sounds. What signs and symptoms exhibited by P.J. are consistent with SLE?

According to the "1997 Update of the 1982 American College of Rheumatology Revised Criteria for Classification of Systemic Lupus Erythematosus," the diagnosis of SLE is satisfied when 4 of 11 criteria are present. The criteria contain 4 cutaneous, 4 systemic, and 3 laboratory components (Table 33-1). P.J. meets criteria with the presence of a positive ANA test result, oral ulcers, presumed pericarditis, and presumed arthritis (joint pain). Furthermore, her clinical features are consistent with SLE including fatigue, alopecia, and low-grade fevers (infection ruled out).

CASE 33-2, QUESTION 2: After P.J. has started treatment and further laboratory tests are performed, what other specialists would you involve in her care at this time?

Rheumatologist and cardiologist because of P.J.'s pericarditis. The cardiologist could evaluate the patient's modifiable cardiovascular risk factors, such as hypertension, dyslipidemia, and obesity. Pericarditis with pericardial effusion is most commonly associated with cardiovascular involvement and SLE. Symptoms could include sharp chest pain and fluid around the heart, worsened with deep breathing and certain body positions. Endocarditis, myocarditis, and valvular disease are less common. Over time, other specialists including gastroenterologist, neurologist, pulmonologist, and nephrologist may be considered as part of P.J.'s multidisciplinary team.

PHARMACOLOGIC AND NON-PHARMACOLOGIC TREATMENTS

The management approach for SLE will depend on the severity of the disease and organ involvement. A therapeutic plan is created based on clinical guidelines for the management, treatment, and monitoring of SLE. It should include considerations for pharmacologic and non-pharmacologic approaches with clearly defined goals. Since there is currently no cure for SLE, the goals of therapy are to prevent flares, treat active symptoms of disease, minimize drug toxicity, and reduce risk of complications and organ damage. An effective and successful therapeutic plan is individualized based on the patient's needs, symptoms, lifestyle, and disease complications. Patients should be regularly monitored by their providers every 3 to 6 months.

NSAIDs and COX-2 Inhibitor

Treatment options will differ depending on the level of severity of SLE. For mild disease, nonselective nonsteroidal anti-inflammatory drugs (NSAIDs) and selective cyclooxygenase-2 (COX-2) inhibitor, such as celecoxib, are used. Because of their ability to inhibit

---

the release of prostaglandins and leukotrienes, NSAIDs and the COX-2 inhibitor possess anti-inflammatory, analgesic, and antipyretic properties. They are effective in reducing swelling, relieving muscle and joint pain, fever, as well as pleuritic chest pain.[26,48] Patients with antiphospholipid antibodies and are at increased risk of thrombosis or atherosclerotic disease may benefit from low-dose aspirin for primary prevention, or long-term anticoagulation therapy for secondary prevention.[7] Long-term use of NSAIDs is encumbered with GI, cardiovascular, and renal issues. Common GI side effects include dyspepsia, heartburn, and nausea. More serious GI symptoms such as stomach bleeding and mucosal lesions may occur. Cardiovascular side effects associated with NSAIDs may include hypertension and the risk of myocardial infarction. Fluid retention and acute tubular necrosis with kidney failure may also occur with long-term use, especially in elderly patients.

As a class, NSAIDs work in the same manner; however, not every agent has the same effect on every patient. When a NSAID is used, it needs to be titrated to its maximal dose over 1 to 2 weeks. The agent should not be discontinued until the patient has been on the maximal dose for at least 2 weeks, which is the amount of time NSAIDs reach maximal efficacy.[27] Although all NSAIDs appear to work in the same way, not every agent has the same effect on every person. In addition, patients may do well with one NSAID for a period of time, then may not derive further benefit from it for some unknown reason. Switching the patient to a different NSAID could produce the desired effects. NSAIDs may be appropriate for chronic pain management in aspirin users provided that appropriate GI prophylactic measures are used in high-risk patients. Patients should use only one NSAID at any given time to really know its benefits.

Celecoxib, a COX-2 inhibitor, is more selective in the inhibition of cyclooxygenase, which is involved in the transformation of arachidonic acid to prostaglandin precursors. Celecoxib has the same efficacy as NSAIDs; however, it possesses a milder GI side effect profile. It does not have a direct effect on platelets.[49] Therefore, it is preferred over NSAIDs in patients with thrombocytopenia. There have been many studies and case reports correlating COX-2 inhibitors with cardiovascular risks (e.g., stroke and heart attack), especially with rofecoxib (Vioxx), which was removed from the U.S. market.[49–51]

CASE 33-2, QUESTION 3: Which of the following treatments would P.J. benefit from using at this time?

P.J. could benefit from high-dose NSAIDs. Traditionally, the initial treatment for SLE pericarditis (inflammation of the lining of the heart or pericardium) is high-dose NSAIDs such as ibuprofen. Patients with SLE are at increased risk for coronary heart disease from increased cardiovascular risk factors (i.e., chronic inflammation, dyslipidemia, obesity, and physical inactivity). SLE patients with recurrent pericarditis will need to be on immunosuppressive medications.

Antimalarials

Antimalarials are currently the mainstay therapy for SLE, in particular hydroxychloroquine sulfate (Plaquenil) and chloroquine. They work through immunomodulation by downregulating the production of TNF alpha and other proinflammatory cytokines.[52] Hydroxychloroquine is preferred over chloroquine because it is associated with less corneal deposition (opacities) and retinopathy risks.[33] Ocular side effects occur in a dose-dependent manner where the risk is low when hydroxychloroquine's dose is less than 600 mg daily and less than 6.5 mg/kg/day. It has anti-inflammatory effects and is used to reduce the time to flare-ups, constitutional (i.e., fever and rashes), skin, fatigue, and joint symptoms.[53] Additionally, hydroxychloroquine has antithrombotic and lipid-lowering effects, which can help patients with SLE.[54] Other ocular symptoms may include blurred vision, night blindness, missing or blanched out areas in the central or peripheral fields, light flashes and streaks, and photophobia. Hydroxychloroquine-related side effects may also include a bull's eye appearance in the macular region.[33] The manufacturer recommends eye exams should be performed at baseline and subsequently every 3 months with long-term hydroxychloroquine treatment. In contrast, the American Academy of Opthalmology (AAO) proposes more flexible eye exam criteria. The AAO recommends patients who are at low risk (those taking hydroxychloroquine less than 6.5 mg/kg/day dose for a treatment duration of less than 5 years) be checked at baseline and then, if normal, every 5 years. Patients who are at high risk (those taking hydroxychloroquine more than 6.5 mg/kg/day dose for >5 years, aged more than 60 years old or pediatric patients, or those with existing retinal disease and kidney or liver disease) should be evaluated at baseline and then annually.[55] Patients should be screened for the presence of "premaculopathy" antimalarial retinopathy, or retinal toxicity during scheduled eye exams because it is a reversible stage as long as hydroxychloroquine is discontinued.

Patients may need to take hydroxychloroquine for months to experience the maximal effect. For SLE, the initial oral hydroxychloroquine dose is 400 mg given daily for 3 to 6 months depending on patient response, then tapered to 200 mg daily for maintenance therapy. If the patient does not have any benefit from hydroxychloroquine after 6 months, the drug should be discontinued.

CASE 33-3

QUESTION 1: R.W., a 54-year-old Caucasian woman with a 30-year history of SLE, returns to her rheumatologist for evaluation. She has received prednisone, hydroxychloroquine, and azathioprine in the past. Her SLE has been stable for 2 years. Feeling well, R.W. discontinued all of her medications more than 1 year ago. She recently returns from a family vacation in the Caribbean. Having been out in the sun for a few hours on the first day, she developed an erythematous eruption over photo-exposed areas of her face, ears, and legs despite the application of sunscreen. R.W. returns home, and the lesions are healing. Though she is fatigued, she feels well enough to return to work. You determine that her rash is because of photosensitivity. What would be the best next step in the management of R.W.?

The next appropriate step is to initiate a short-course of low-dose prednisone because it can be used to treat a photosensitive rash from SLE. The rash may occur because with SLE, the body’s immune system does not function properly, and the inflammatory response works to damage the patient’s own tissues. Prednisone is a corticosteroid that helps to reduce the inflammation and immune response, thereby preventing further damage to the tissues in the body.

CASE 33-3, QUESTION 2: The rash resolves; however, R.W. continues to complain of fatigue and arthralgia. No other clinical signs or symptoms consistent with SLE flare emerge. Laboratory test results reveal continued elevation of anti-dsDNA antibody titers and suppressed complement levels. What is your next step in managing R.W.?

Hydroxychloroquine should be initiated as it is effective for long-term treatment of SLE with rash, fatigue, and arthralgias. Hydroxychloroquine is often prescribed in combination with steroids to reduce the dose required of the steroids. It is prescribed for skin rashes, mouth ulcers, and joint pain. Hydroxychloroquine improves SLE by decreasing autoantibody production, protecting against the damaging effects of ultraviolet light from the sun and other sources, and improving skin lesions. Several studies have reported the benefits of hydroxychloroquine in treating symptoms of SLE, preventing disease flares, and its association with less organ damage.[56]

CASE 33-3, QUESTION 3: R.W. is initiated on hydroxychloroquine 400 mg orally daily. How long should she be on the initial treatment dose?

Three to six months of the initial treatment dose of hydroxychloroquine is recommended unless R.W. does not tolerate the side effects or does not benefit from the medication. After R.W. has responded to the initial dose, then hydroxychloroquine can be tapered to 200 mg daily for maintenance therapy.

CASE 33-3, QUESTION 4: How often should eye exams be performed for R.W.?

At high doses of hydroxychloroquine and over time, it may damage the retina of the eye (retinal toxicity), causing vision problems. Eye exams should be performed at baseline before initiating hydroxychloroquine and every 3 months based on the manufacturer’s recommendation. If based on the AAO, an eye exam should be performed at baseline and then every 5 years. If low doses of hydroxychloroquine are used in the treatment of SLE, the risk of retinal toxicity is low. Long-term users of high-dose hydroxychloroquine will need to monitor their eye health regularly to prevent retinal toxicity.

CASE 33-3, QUESTION 5: What are the goals of SLE treatment?

Since there is no cure for SLE, the goals of treatment are to reset the patient's immune system to a state of remission, reduce the incidence of drug toxicity, and prevent multi-organ damage.

Corticosteroids

Corticosteroid treatment is considered for patients with SLE who have not responded to NSAIDs and hydroxychloroquine. Corticosteroids possess anti-inflammatory effects and work by inhibiting T and B cell responses.[57] They provide immediate relief for mild-to-moderate symptoms compared to immunosuppressant treatments. Low-dose corticosteroid, such as prednisone, may be effective for mild-to-moderate symptoms. For instance, low-dose oral prednisone (6–10 mg daily) over a duration of 4 to 6 weeks is recommended for mild disease activity. Short-term use of tapered courses of prednisone will help reduce acute flares with or without systemic symptoms starting at adult doses of 1 mg/kg/day, up to 60 mg daily, and tapered over 8 weeks. Short-term treatment can minimize risks of developing side effects associated with long-term corticosteroid use, such as weight gain, decreased bone mineral density, muscle wasting, hypercholesterolemia, and hyperglycemia. More severe adverse effects associated with long term use of high-dose corticosteroids may include diabetes, osteoporosis, mood changes (e.g., anxiety, insomnia, depression, and delirium), Cushing's syndrome, and risks of cardiovascular events. Topical corticosteroids are recommended for cutaneous SLE manifestations. Adjunctive treatments with NSAIDs or celecoxib may be combined with prednisone to reduce its dose and side effects, or allow it to be administered as an every other day therapy. High-dose oral corticosteroids (e.g., prednisone 40–60 mg daily) or intravenous corticosteroids (e.g., methylprednisolone 0.5–1.0 g daily) are considered for more severe disease.[27]

CASE 33-3, QUESTION 6: If R.W. is to be initiated on chronic, high-dose corticosteroid therapy for management of her SLE symptoms, what should she be monitored for?

With the use of high-dose corticosteroids, it important to monitor for weight gain, hyperglycemia, osteoporosis, glaucoma, cataracts, hypercholesterolemia, mood changes, and premature atherosclerosis. Steroid medications can have serious long-term side effects, and the risk of the side effects increases with higher doses and chronic therapy.

Disease-Modifying Antirheumatic Drugs (DMARDs)

Methotrexate (MTX, Rheumatrex, Trexall) is a folate antagonist that inhibits dihydrofolate reductase, an essential enzyme for DNA synthesis. MTX is usually considered for treatment of rheumatoid arthritis, in terms of arthritis and skin manifestations. It is an effective alternative agent to hydroxychloroquine and corticosteroids for SLE patients with arthritis, rash, or serositis.[53,58,59] When used with or without corticosteroids, MTX is dosed between 7.5 mg and 15 mg weekly, orally or subcutaneously, not to exceed 25 mg/week. Subcutaneous injection is recommended for patients who experience drug-induced nausea. Side effects are dose dependent and can range from mild to severe. Mild side effects include gastrointestinal effects (e.g., nausea and vomiting) versus leukopenia or thrombocytopenia which are more severe side effects. Hepatotoxicity could occur from MTX use. Patients should receive baseline liver function tests and periodically throughout therapy. They should also be screened for preexisting liver disease, excessive alcohol use, or diabetes. Patients with liver disease (e.g., hepatitis B or C) should avoid MTX because of liver toxicity risk. Similarly, MTX should be used cautiously in patients with renal disease because of increased risk for renal toxicity. Other adverse effects may include lung toxicities, such as cough, shortness of breath, and pulmonary infiltrates.[53,58] MTX is teratogenic and contraindicated in pregnant women (Pregnancy Category X). Men and women who take MTX should stop 1 to 3 months before trying to conceive. The 3-month period allows the complete elimination of MTX from the body.

Leflunomide (Arava) is a pyrimidine synthesis inhibitor that inhibits the formation of DNA in the cells of the body, particularly the immune cells that contribute to the inflammation, swelling, stiffness, and joint pain. Leflunomide can be used as a steroid-sparing treatment for SLE patients with photosensitive rashes and arthritis. It is also used either as monotherapy or in combination with MTX. Treatment may be initiated with or without a loading dose, depending on the patient’s risk for ARAVA-associated hepatotoxicity and ARAVA-associated myelosuppression. [60] Patients who are at a low risk for ARAVA-associated hepatotoxicity and ARAVA-associated myelosuppression, the oral loading dose is 100 mg daily for 3 days, followed by a maintenance oral dose of 20 mg daily. Alternatively, an oral loading dose of 100 mg once a week for 3 weeks, in addition to the maintenance dose have been used to reduce the increased incidence of diarrhea. If diarrhea persists to be a bothersome side effect, in spite of the use of antidiarrheal medication, then the dose can be reduced to 10 mg daily. In contrast, patients who are at a high risk for ARAVA-associated hepatotoxicity (i.e., concomitant MTX use) or ARAVA-associated myelosuppression (i.e., concomitant immunosuppressant use) should receive an oral dose of 20 mg daily without a loading dose.[60] Similar to MTX screening, patients initiated on leflunomide should receive baseline liver function tests and complete blood count tests every 3 to 4 months. Furthermore, they should also be screened for preexisting liver disease and excessive alcohol use. Leflunomide is teratogenic and contraindicated in pregnant women (Pregnancy Category X). Women should use oral contraceptives or other forms of effective birth control methods while taking the drug. More importantly, they should continue to do so until 2 years after discontinuation of leflunomide since its active metabolite, teriflunomide, remains in the plasma. Cholestyramine (Questran) can be used to accelerate the elimination of leflunomide and reduce the plasma levels of teriflunomide.[61]

Immunosuppressants

Azathioprine (Imuran, Azasan), a purine analog, inhibits DNA synthesis and blocks cell proliferation.[58] It is used to treat non-renal SLE manifestations, such as photosensitive rashes. Prior to starting azathioprine treatment, genotyping or phenotyping of the thiopurine S-methyltransferase (TPMT) is strongly recommended.[62] Caution is recommended for patients with reduced thiopurine methyltransferase activity because they may be at increased risk of bone marrow suppression.[57,63] Patients who are homozygous, or carry two nonfunctional TPMT alleles will experience life-threatening myelosuppression when treated with azathioprine because of high concentrations of thioguanine nucelotides. Bone marrow suppression can occur in any patient, is dose-dependent, and is reversible by reducing the dose of azathioprine.[64] Side effects include gastrointestinal (e.g., nausea, vomiting, diarrhea, and stomach pain) and leukopenia. Anemia and thrombocytopenia may result from high doses of azathioprine or from poor metabolizers of the drug.

Mycophenolate mofetil (MMF; CellCept) inhibits inosine monophosphate dehydrogenase, an essential enzyme for DNA synthesis in lymphocytes. Its active metabolite inhibits the proliferation of T and B cells.[57] Similar to methotrexate, MMF treatment could be used to treat SLE patients with arthritis. It is also used for SLE patients with renal symptoms. It has been demonstrated to be superior to azathioprine as maintenance therapy of LN.[65] Patients with SLE and nephritis had a much better response with a 6-month induction trial of mycophenolate versus azathioprine for prolonging time to treatment failure, time to renal flare, and time to rescue therapy. MMF is teratogenic (Pregnancy Category D) and should not be used in pregnant women or who plan to become pregnant. It could cause birth defects and reduces the effectiveness of oral contraceptives. Women who take this drug should wait at least 1 to 3 months after stopping the drug before trying to conceive. Common side effects may include gastrointestinal (e.g., nausea, vomiting, and diarrhea), risk of infection, and decreased white blood cell counts.[53]

CASE 33-3, QUESTION 7: R.W.'s daughter has also been diagnosed with SLE. She is 28 years old and is married. She and her husband want to start a family. R.W. heard about MMF as one of the treatment options for SLE. She asks you if her daughter can benefit from taking MMF.

You explain that MMF is not an option because it is teratogenic and has been associated with infertility even though it is classified as Pregnancy Category D.

Furthermore, MMF has been reported to cause risk of birth defects if taken during pregnancy (i.e., cleft lip/palate or ear malformations). Women who take this drug should wait at least 1 to 3 months after stopping the drug before trying to conceive.

Cytotoxic Drug

Cyclophosphamide (Cytoxan) is an alkylating agent. Its active metabolite, aldophosphamide, interferes with DNA links and causes cell death.[52] It is the agent of choice for treatment of LN, severe CNS, lung, or hematologic manifestations.[53,66] It is teratogenic (Pregnancy Category D) and should not be used in pregnant women or who plan to become pregnant. Cyclophosphamide has been reported to cause birth defects, especially if taken during the first trimester. Birth defects may include growth restriction, ear and facial abnormalities, hypoplastic limbs, and absence of digits.[67] Cyclophosphamide has a serious adverse effect profile that includes hemorrhagic cystitis, bacterial and viral (herpes zoster) infections, and infertility. Its metabolite, acrolein, is toxic to the bladder. Hemorrhagic cystitis and bladder cancer risks can be minimized by hydrating the patient (orally and intravenously), frequent bladder emptying, and using mesna as a protectant prior to intravenous use.[53] Mesna (sodium 2-mercaptoethane sulfonate) is a sulfhydryl donor which binds and detoxifies acrolein.[68] Urinalysis testing and monitoring for hematuria should be performed regularly. If patient develops hemorrhagic cystitis, cyclophosphamide therapy should be discontinued. The risk of bladder cancer is increased after receiving a total dose of 30 g.[58]

Because immunosuppressants and cyclophosphamide can increase the prevalence of secondary malignancies, such as cervical cancer in female patients with SLE, the ACR recommends annual Pap exams as part of laboratory monitoring.[53,69] Infertility, from ovarian failure in females or azoospermia in males, can occur in patients with SLE and of childbearing age.[7] Gonadotropin-releasing hormone analogs may preserve gonadal protection and can be considered for patients who are concerned with infertility associated with cyclophosphamide.

CASE 33-3, QUESTION 8: R.W. asks you what other commonly used drugs for SLE treatment should her daughter avoid taking if she wanted to become pregnant.

Other than MMF, her daughter should avoid taking leflunomide (Pregnancy Category X), MTX, (Pregnancy Category X), and cyclophosphamide (Pregnancy Category D) for treatment of her SLE if she plans to get pregnant. Women should use oral contraceptives or other forms of effective birth control methods while taking leflunomide. More importantly, they should continue to do so until 2 years after discontinuation of leflunomide since its active metabolite, teriflunomide, remains in the plasma. Cholestyramine (Questran) can be used to accelerate the elimination of leflunomide and reduce the plasma levels of teriflunomide.[61] Men and women who take MTX should stop 1 to 3 months before trying to conceive. The 3-month period allows the complete elimination of MTX from the body. Cyclophosphamide has been reported to cause birth defects, especially if taken during the first trimester. Birth defects may include growth restriction, ear and facial abnormalities, hypoplastic limbs, and absence of digits.[65]

CASE 33-3, QUESTION 9: Over the next couple of months, R.W. continues to have mild-to-moderate flares of her skin and joints because of SLE, despite hydroxychloroquine therapy. Her primary care physician is considering cyclophosphamide for her. What common toxicity should R.W. be monitored for?

R.W. should be monitored for bladder toxicity. Acrolein, a compound of one of cyclophosphamide's active metabolite aldophosphamide, is toxic to the bladder epithelium and could cause hemorrhagic cystitis.[70] Hemorrhagic cystitis is associated with hematuria and occasional dysuria.

CASE 33-3, QUESTION 10: How is the risk for bladder toxicity reduced?

By administering mesna and plenty of fluids (orally and intravenously) the risk of bladder toxicity is reduced. Mesna (sodium 2-mercaptoethane sulfonate) is a sulfhydryl donor that binds and detoxifies acrolein. Pulsed or intermittent dosing of cyclophosphamide can decrease the cumulative drug dose and reduce bladder exposure to acrolein.

CASE 33-3, QUESTION 11: Considering her present symptoms, should R.W. be initiated on cyclophosphamide?

Because her symptoms are still mild to moderate without signs of CNS, lung, or renal complications, cyclophosphamide is not recommended. Cyclophosphamide is primarily reserved for treatment of LN, severe CNS associated with SLE, lung, or hematologic manifestations.

Biologic Therapy

Belimumab (Benylsta) is the first biologic agent approved for adjunctive treatment of SLE in patients with active, autoantibody-positive SLE. It is a human IgG1 lambda monoclonal antibody that stimulates B-lymphocytes (BLyS). Belimumab is also referred to as a B cell–activating factor (BAFF)-specific inhibitor. B cells have three membrane receptors: B cell–maturation antigen, transmembrane activator and calcium modulator and cyclophilin ligand interactor, and BAFF receptor.[18] BAFF is involved in B cell survival, activation, and differentiation. It is elevated in patients with B cell–mediated autoimmune diseases, such as SLE.[71] Belimumab is hypothesized to decrease the amount of abnormal B cells.

Phase II clinical trials reported that belimumab combined with standard therapy offered better response to patients with active SLE versus standard therapy alone.[71,72] Belimumab's efficacy was further demonstrated in two phase III randomized, placebo-controlled clinical trials (BLISS-52 and BLISS-76). A total of 1,684 patients were randomized to receive either belimumab or placebo in combination with standard therapy.[73,74] The combination of belimumab and standard therapy was found to be superior to placebo plus standard therapy. Furthermore, the combination of belimumab and standard therapy was well tolerated, improved SLE Responder Index response rates, and reduced disease activity and severe flares.[73,74] Belimumab has not been studied in patients with severe active LN or severe active CNS lupus; therefore, it cannot be recommended for use in patients with these symptoms. More importantly, it is not recommended to be administered in combination with other biologics or intravenous cyclophosphamide because it has not been studied in these settings.

Possible side effects (≥5%) of belimumab may include diarrhea, nausea, fever, insomnia, nasopharyngitis, pharyngitis, bronchitis, extremity pain, migraine, and depression.[75,76] More common side effects reported from the belimumab study group were serious infections, primarily upper respiratory tract infections.[75] Therefore, patients being treated for chronic infections should not start belimumab therapy. If an infection develops while receiving belimumab, temporary discontinuation of the drug is recommended. From clinical trials, mortality (resulting from infection, cardiovascular disease, and suicide) was increased in patients receiving belimumab versus those on placebo therapy.[71–74] Hypersensitivity reactions, including infusion reactions and anaphylaxis, may occur. Patients should be closely monitored for potential side effects and reactions.

Belimumab is administered parenterally as an intravenous infusion over 1 hour (Table 33-3). Premedication with an antihistamine for prophylaxis against infusion-related reactions and hypersensitivity reactions is recommended as part of the therapy. There are no dosage adjustments required for patients with hepatic and renal impairment.

CASE 33-3, QUESTION 12: Over the next year, R.W. continues to have bothersome symptoms associated with her SLE, despite hydroxychloroquine therapy. She resists the recommendation to use steroids because of risks of weight gain, osteoporosis, and vision problems. She is excited to hear about a recently approved drug for SLE, belimumab. R.W. asks you for the mechanism of action of belimumab.

Belimumab is a monoclonal antibody that inhibits the B cell–survival factor, B-lymphocyte stimulator (BLyS). As a BLyS-specific inhibitor, belimumab blocks the binding of BLyS to receptors on B cells, thus inhibiting the survival of B cells including autoreactive B cells. It also reduces the differentiation of B cells into immunoglobulin-producing plasma cells. Belimumab reduces disease activity and possibly a number of severe flares and steroid use when administered in combination with standard therapy. It is approved for treatment of patients with active, autoantibody-positive lupus in combination with standard therapies (i.e., hydroxychloroquine, azathioprine, and MTX).

Table 33-3

Preparation and Administration Instructions of Belimumab[18,76]

Reconstitution

Remove belimumab vial from refrigerator and allow it to stand for 10 to 15 minutes to reach room temperature.
Reconstitute belimumab powder with Sterile Water for Injection, USP, as follows, with reconstituted solution to make a concentration of 80 mg/mL belimumab.
Reconstitute 120 mg vial with 1.5 mL sterile water.
Reconstitute 400 mg vial with 4.8 mL sterile water.
Direct the stream of sterile water to the side of the vial to minimize foaming.
Gently swirl the vial for 60 seconds. Allow vial to sit at room temperature during reconstitution, gently swirling the vial every 5 minutes until powder is dissolved. Do not shake. It usually takes 10–15 minutes, but it may take up to 30 minutes. Protect solution from light.
If a mechanical reconstitution device (swirler) is used to reconstitute belimumab, it should not exceed 500 rpm, and the vial should not be swirled for longer than 30 minutes.
Once reconstitution is complete, the solution should be opalescent and colorless to pale yellow and without particles. Small bubbles can occur and are acceptable.

Dilution Instructions

Belimumab should only be diluted with 0.9% sodium chloride injection, USP (normal saline). Dextrose IV solutions are incompatible with belimumab. Dilute the reconstituted product to 250 mL in normal saline for IV infusion. From a 250-mL infusion bag or bottle of normal saline, withdraw and discard a volume equal to the volume of the reconstituted solution of belimumab required for the patient's dose. Then add the required volume of reconstituted solution into the infusion bag or bottle. Discard any unused solution.
Inspect visually for any particular matter and discoloration before administration. Discard if present.
Use reconstituted solution immediately, otherwise it should be stored protected from sunlight and refrigerated at 2°C–8°C (36°F–46°F). Solutions of belimumab diluted in normal saline may be stored at 2°C–8°C (36°F–46°F) or room temperature. The time from reconstitution to completion of infusion should not exceed 8 hours.
No incompatibilities exist between belimumab and polyvinyl chloride or polyolefin bags.

Administration Instructions

Administer the diluted solution of belimumab by IV infusion only, over a period of 1 hour.
Belimumab should be administered by health care professionals prepared to manage anaphylaxis.
Do not infuse belimumab concomitantly in the same IV line with other agents.

IV, intravenous; USP, US Pharmacopoeia.

CASE 33-3, QUESTION 13: How is belimumab dosed and administered?

Belimumab is given at a recommended dose of 10 mg/kg that is administered intravenously as an infusion over 1 hour, 2 weeks apart for the first three doses, and 4 weeks apart thereafter.

CASE 33-3, QUESTION 14: What are the necessary precautions taken prior to administration of belimumab?

Antihistamine premedication is recommended as a prophylaxis to prevent infusion reactions and hypersensitivity reactions. Patients should be monitored before and after drug administration. Belimumab should be used with caution in patients with chronic infections. Infections were the most common adverse events associated with belimumab in BLISS-52 and BLISS-76 clinical trials. Upper respiratory tract infections were the most common type, occurring in more than 5% of belimumab patients.

CASE 33-3, QUESTION 15: When is belimumab not recommended for use in patients with SLE?

Belimumab is not recommended in patients with severe active lupus nephritis, or in those with severe active CNS lupus as its efficacy has not been evaluated in these types of patients. Furthermore, depression and suicidality have been reported in clinical trials; therefore, it is not recommended for patients with uncontrolled psychiatric disorders. Belimumab is not recommended in combination with other biologics or IV cyclophosphamide as it has not been studied with these drugs.

CASE 33-3, QUESTION 16: Are there drug–drug interactions between belimumab and other combination treatments for SLE?

There are no clinically significant drug–drug interactions identified with belimumab in the clinical trials. It was administered concomitantly with corticosteroids, antimalarial drugs, statins, NSAIDs, angiotensin-converting enzyme inhibitors, and immunomodulatory and immunosuppressive agents.

CASE 33-3, QUESTION 17: Can R.W. receive immunizations while receiving belimumab treatment?

Live vaccines should not be administered within 30 days before treatment starts or during treatment. Belimumab may interfere with R.W.'s response to immunizations.

Table 33-4 summarizes the current medications used for treating SLE.[53,57,69,75,76] There are drug interactions with the medications used for treating SLE symptoms. Table 33-5 summarizes the possible significant drug–drug interactions.[77,78]

Non-pharmacologic Therapy

Both the ACR and EULAR recommend non-pharmacologic treatments as part of the management of SLE.[22,79] Sunscreens with a sun protective factor of 15 or greater should be used daily. There are patients who are sensitive to UVA light and may require broader-spectrum sunscreens. Patients are advised to apply sunscreen each morning and prior to sun exposure. Wearing protective clothing and/or sun avoidance for patients with SLE is encouraged. Sunbathing and the use of sunbeds in tanning parlors are discouraged. In addition, patients with SLE should be educated about lifestyle modifications, such as smoking cessation, weight control, and regular exercise to reduce comorbidities of atherosclerosis, hypertension, and diabetes.[7]

Psychosocial support is also an important aspect of management as the disease and several of the medications may cause depression and anxiety. The medications' side effects can also affect a patient's adherence to treatment and medical office visits.

DRUG-INDUCED LUPUS ERYTHEMATOSUS

Drugs can cause subacute cutaneous lupus erythematosus or drug-induced lupus (DIL) (<1%) by inducing autoantibodies.[4] For as many patients that develop these antibodies, a surprisingly low number of them do not develop signs of an autoantibody-associated condition.[2] Over 38 drugs have been implicated with causing the disease (Table 33-6).[42,80–82] However, most DIL cases have been associated with the following medications: hydralazine, procainamide, and quinidine.

The symptoms of DIL may present as arthralgia or myalgias, fatigue, and the presence of anti-histone antibodies. The symptoms are similar to those of SLE; however, they are generally not as severe. Typically, the symptoms are self-limiting and resolve after discontinuing the offending drug. NSAIDs may be used to help speed up the healing process. Corticosteroids may also be used if more severe symptoms of DIL are present. The development of DIL occurs over long-term and from chronic use of medications that have high risk for causing lupus.

The mechanism by which these drugs exert their effect is not well understood. However, it may be attributed to a patient's genetic predisposition as a slow acetylator, which decreases the metabolism of some drugs such as procainamide and hydralazine. Gene expression is regulated by DNA methylation and histone modifications.[81,82] Procainamide and, particularly, hydralazine are hypothesized to inhibit DNA methylation, which alters gene expression in T lymphocytes. Subsequently, this process induces an over-expression of lymphocyte function-associated antigen 1 (LFA-1 antigen), thus resulting in autoreactivity.[28,80]

INVESTIGATIONAL AGENTS

Aside from the current therapies used for the treatment and management of SLE symptoms, rituximab and abatacept are currently being studied in patients with SLE. Both medications target T and B cells and have already been approved for the treatment of rheumatoid arthritis along with other indications. More recently, investigational biologic agents are being developed and are undergoing Phase I, II, and III clinical trials. These newer biologic agents specifically target different phases of the pathogenesis of SLE, have different mechanisms of action, and possess milder adverse effect profiles. The investigational drug classes include immune cell–

targeted therapies, anti-cytokine therapy, therapies targeting costimulatory signaling pathways, and neutralizing monoclonal antibody against interferon alpha.[57]

TREATMENT APPROACHES

The primary goal of treatment for SLE is to control acute flares, and maintenance strategies are used to suppress symptoms and to prevent further organ damage. NSAIDs, hydroxychloroquine, and low-dose corticosteroids are considered maintenance therapy to control mild-to-moderate symptoms of arthritis, dermatitis, and constitutional symptoms. High-dose systemic corticosteroids, DMARDs, immunosuppressants, and belimumab are used for patients with more serious active disease, including those with more life-threatening forms such as LN.[66] Certain DMARDs and immunosuppressants (i.e., leflunomide, MTX, cyclophosphamide, and MMF) should be used with extreme caution in women of childbearing age and in those who are planning to get pregnant because of teratogenic effects.[7] MMF is the preferred maintenance therapy for LN in patients who can tolerate the medication, who are not pregnant, and who respond to it. It can reduce the effectiveness of oral contraceptives and, thus, additional or alternative non-hormonal methods of birth control should be considered. Currently, only hydroxychloroquine and belimumab are FDA-approved for the treatment of SLE. Immunosuppressants and DMARDs (i.e., azathioprine, cyclophosphamide, leflunomide, MTX, and MMF) have been used off-label for managing SLE symptoms for years. Prophylaxis with aspirin or long-term anticoagulation should be considered for patients with antiphospholipid antibodies and who are at an increased risk of thrombosis.[18] Patients with mild disease require frequent medical evaluations every 3 to 6 months. On the contrary, patients with inactive disease may benefit from being monitored every 6 to 12 months.

Table 33-4

Medications Used for the Treatment of Systemic Lupus Erythematosus[53,57,69,75,76]

Medication	FDA-Approved for SLE	Dose	Side Effects/Toxicities	Monitoring Parameters
Azathioprine	No; off-label	1–3 mg/kg/day	Bone marrow suppression, liver toxicity, elevated lymphocytes	Clinical: symptoms of infection. Laboratory: CBC and platelet count every 1–2 weeks with initiation and dosage changes,

				then every 1–3 months; monitor LFTs and Scr; Pap test at regular intervals.
Belimumab	Yes	IV: 10 mg/kg every 2 weeks for the first 3 doses and then administer monthly	Serious infusion and anaphylactic reactions; depression with suicidal ideation	Clinical: symptoms of allergic reaction, including hypotension, angioedema, rash, urticarial, pruritus, and difficulty breathing. Symptoms of common infusion reactions, including headache, nausea and skin reactions. Symptoms of infection, including fever, nausea, diarrhea; chest pain or shortness of breath. Laboratory: CBC monthly.
Corticosteroids	No; off-label	Prednisone (or equivalent) 0.125–1 mg/kg/day	Elevated blood pressure, glucose and cholesterol levels; low potassium or reduced potassium levels; reduced bone density; cataracts; weight gain; infections; and fluid retention	Clinical: symptoms of high blood sugar, edema, shortness of breath, high blood pressure, visual changes, bone pain. CNS symptoms of depression, suicidal ideation, insomnia, or other mood changes can occur at higher doses (e.g., prednisone >60 mg). Laboratory: glucose every 3–6 months, cholesterol annually, BP at each visit, bone density.
Cyclophosphamide	No; off-label	IV: 0.5–1 g/m^2 monthly; Oral: 1–2 mg/kg/day	Bone marrow suppression, malignancy, immunosuppression, hemorrhagic cystitis, secondary infertility	Clinical: symptoms of infection and presence of blood in urine. Laboratory: CBC and urinalysis monthly, urine cytology and Pap test annually for life.
Hydroxychloroquine	Yes	200–400 mg twice daily	Ophthalmic damage	Clinical: visual changes. Laboratory: funduscopic and visual field exam, frequency determined by risk.
Leflunomide	No; Off-label	Loading dose: 100 mg daily × 3 days, followed by 20 mg daily; Or 100 mg weekly × 3 weeks, then 20 mg daily ARAVA-associated hepatotoxicity or ARAVA-associated myelosuppression: 20 mg daily without a loading dose	Diarrhea, nausea, rash, liver toxicity, myelosuppression	Clinical: frequency and severity of diarrhea. Laboratory: LFTs, CBC
Methotrexate	No; off-label	Oral: 5–15 mg as a single weekly dose,	Bone marrow suppression, lung	Clinical: symptoms of infection, shortness of breath, nausea,

		or can be given as 3 divided doses/week given every 12 hours (i.e., 2.5 mg × 3 doses with 12 hours apart)	and liver toxicity, infection	vomiting. Laboratory: initial chest x-ray, CBC and platelet count monthly, LFTs, albumin, Scr every 4–8 weeks.
Mycophenolate mofetil	No; off-label	1,000–3,000 mg daily	Bone marrow suppression, liver toxicity and infection	Clinical: symptoms of infection. Laboratory: CBC and platelet count every 1–2 weeks with initiation and changes in dosage (then every 1–3 months), monitor LFTs and Scr, monitor changes in BP.
NSAIDs	No; off-label[a]	Product dependent	Gastrointestinal bleeding, liver and kidney toxicity, elevated blood pressure	Clinical: dark/black stool, upset stomach, nausea, vomiting, abdominal pain, edema. Laboratory: CBC, LFTs and Scr annually; BP at each visit.

[a] Aspirin is approved for treatment of SLE.

NSAIDs, nonsteroidal anti-inflammatory drugs; BP, blood pressure; CBC, complete blood count; IV, intravenous; LFTs, liver function tests; SCr, serum creatinine.

Table 33-5

Summary of Drug Interactions with Medications for Systemic Lupus Erythematosus [77,78]

Medication	Possible Interaction with Concomitant Drugs
Azathioprine	Allopurinol, cyclosporine, etanercept, infliximab, leflunomide, sirolimus, tacrolimus
Belimumab	Drug interactions have not been formally studied
Corticosteroids	Cimetidine, cisapride, clarithromycin, dihydroergotamine, ergotamine, erythromycin, itraconazole, ketoconazole, lovastatin, mifepristone, quinidine, rifabutin, rifampin, simvastatin, sirolimus, St. John’s wort, terfenadine, tofacitinib
Cyclophosphamide	Carbamazepine, etanercept, tofacitinib
Hydroxychloroquine	Antacids, azathioprine, cyclosporine, digoxin, etanercept, infliximab, leflunomide, mycophenolate, sirolimus, tacrolimus
Leflunomide	Azathioprine, cyclosporine, etanercept, infliximab, methotrexate, mycophenolate, sirolimus, tacrolimus
Methotrexate	Celecoxib, diclofenac, etodolac, ketorolac, leflunomide, meloxicam, probenecid, sulfamethoxazole, trimethoprim
Mycophenolate mofetil	Ampicillin, antacids, cholestyramine, colestipol, etanercept, ethinylestradiol, infliximab, leflunomide, nafcillin, quinidine, sirolimus, tacrolimus
NSAIDs	ACE inhibitors, angiotensin receptor blockers, beta blockers, diuretics, other

	antihypertensives, lithium

ROLE FOR PHARMACISTS

SLE disease is very complex and the symptoms are variable. Successful and effective management of SLE requires the involvement of a multidisciplinary healthcare team comprised of many specialists (e.g., rheumatology, cardiology, nephrology, dermatology, psychology, and ophthalmology) and pharmacists. Pharmacists have an important role in caring for patients with SLE, especially with education, management of their medications, and the monitoring of drug–drug or drug–herbal interactions. As part of the healthcare team, pharmacists can provide drug education and counseling to patients with respect to proper administration of the medications, common side effects, management of the side effects, and reinforcement of adherence to their medications and office visits. Education and counseling of the teratogenic effects of certain DMARDs and immunosuppressants should be offered, as well as the information that the disease should remain inactive for at least 6 months prior to attempting to conceive.[53] More importantly, pharmacists can provide education to help patients with SLE maintain a healthy lifestyle and better quality of life (e.g., regular weight-bearing exercise, sufficient dietary vitamin intake, smoking cessation, and limited alcohol intake to a minimum of two drinks daily).[83,84]

CASE 33-4

QUESTION 1: S.P., a 35-year-old Asian woman with a 10-year history of SLE, sees you for follow-up management of her medications. She currently takes hydroxychloroquine 200 mg PO daily as part of her maintenance regimen. S.P. reports experiencing some heartburn and bloating symptoms over the past several days and purchased an over-the-counter antacid, Tums. Tums helped to alleviate her gastrointestinal symptoms; however, she notices feeling more fatigued lately. What is the potential drug interaction between hydroxychloroquine and Tums?

Antacids that contain calcium carbonate, magnesium, or aluminum (i.e., Tums, Maalox) can interfere with the absorption of hydroxychloroquine and reduce its effectiveness when taken at the same time.

CASE 33-4, QUESTION 2: As her pharmacist, provide advice to S.P. regarding the appropriate administration of hydroxychloroquine and Tums?

Table 33-6

Medications that may Cause Systemic Lupus Erythematosus (DIL)[81–/>83]

Drug Class	Very Low Risk	Low-to-Moderate Risk	High Risk
Antiarrhythmics	Disopyramide, propafenone	Quinidine	Procainamide

Antimicrobials/antibiotics	Nitrofurantoin	Isoniazid, minocycline	
Anticonvulsants	Phenytoin, primidone, ethosuximide	Carbamazepine	
Antihypertensives	Enalapril, clonidine, atenolol, labetolol, pindolol, minoxidil, prazosin, chlorthalidone, hydrochlorothiazide	Captopril, methyldopa, acebutolol	Hydralazine
Anti-inflammatories	Phenylbutazone	Sulfasalazine, D-penicillamine	
Antipsychotics	Perphenazine, phenelzine, chlorprothixene, lithium	Chlorpromazine	
Anti-thyroids		Propylthiouracil	
Miscellaneous	Lovastatin, levodopa, alpha-interferon, timolol eye drops		

S.P. should be advised to separate the administration of hydroxychloroquine and Tums by at least 4 hours to reduce the risk of a drug interaction. There has been no clinically significant drug–drug interactions reported for concomitant use of hydroxychloroquine and histamine (H_2) receptor antagonists.

CASE 33-4, QUESTION 3: What other counseling points could you offer to S.P. about her health?

S.P. should be advised to incorporate a heart-healthy exercise regimen (low-impact aerobic exercise, such as walking, swimming, or Pilates) and diet (low-sodium, low-fat, and low-carbohydrate) to reduce modifiable cardiovascular risk factors and on approaches to maintain adequate rest. Counseling should also be provided regarding the use of sunscreen, vitamin D supplementation and adequate calcium intake, smoking cessation, maintenance of schedule immunizations, and prompt management of infections.

Kidney and Liver Transplantation

David J. Taber and Robert E. Dupuis

	CORE PRINCIPLES	CHAPTER CASES
1	Successful kidney transplantation involves rigorous evaluation of both donor and recipient. This results in immunologic categorization as either a high-risk or low-risk transplant and determines the immunosuppressive regimen an individual recipient should receive. The majority of these patients will receive combination therapy, which includes a calcineurin inhibitor, an antiproliferative agent, and a corticosteroid.	**Case 34-1 (Questions 1, 2), Table 34-1**
2	Induction therapy is used in most kidney transplant cases. Rabbit antithymocyte globulin, alemtuzumab, and basiliximab are common agents. Differences among these agents include dosing regimen and side effect profile. Rabbit antithymocyte globulin and alemtuzumab are often used in high-risk patients, including those with delayed graft function, whereas basiliximab is frequently used in low-risk recipients.	**Case 34-1 (Questions 2–6)**
3	Immunosuppressive combination therapy is directed at prevention of rejection. Acute rejection can be either T-cell-mediated or B-cell-mediated. T-cell-mediated rejection can be successfully treated, whereas B-cell-mediated rejection is much more resistant. Despite success in reducing acute rejections, chronic rejection and chronic graft dysfunction are major causes of graft loss.	**Case 34-1 (Questions 7–9)**
4	Cyclosporine is a calcineurin inhibitor with a complex pharmacokinetic profile associated with multiple adverse effects and requires therapeutic drug monitoring (TDM). Its use has significantly declined since the introduction of tacrolimus.	**Case 34-2 (Questions 1, 2), Case 34-3 (Question 1) Case 34-4 (Question 1)**
5	The mTOR inhibitors, sirolimus and everolimus, have complex pharmacokinetic profiles, significant adverse effects, and require TDM. These agents appear to be most useful in minimizing or avoiding the use of calcineurin inhibitors or other agents.	**Case 34-4 (Question2)**
6	The calcineurin inhibitors cyclosporine and tacrolimus and steroids have significant toxicity profiles, particularly with chronic long-term use. Calcineurin inhibitor-induced nephrotoxicity is a major problem. Steroids have a negative impact on the cardiovascular, bone, and endocrine system. Several strategies have been developed in an attempt to either avoid or minimize these adverse effects.	**Case 34-2 (Questions 1, 2), Case 34-3 (Question 1)**
7	Cardiovascular complications, including hypertension, hyperlipidemia, and	**Case 34-5 (Questions 1–4)**

	diabetes, are prevalent among kidney transplant recipients. These contribute to poor patient survival and graft loss. Other complications such as osteoporosis are frequently observed. Monitoring and treatment of these complications, which may be drug-induced, are an important part of the post-transplant care plan.	
8	BK polyomavirus is almost exclusively seen in kidney transplantation and is associated with graft loss. The best approach to reducing its occurrence is viral surveillance. If it is present, then reduction of immunosuppression appears to be the most effective treatment.	**Case 34-6 (Questions 1–3)**
9	Liver transplantation is considered the treatment of choice for patient with end-stage liver disease. Common early post-transplant complications include surgical (biliary leaks and bleeding), neurologic (continued hepatic encephalopathy, drug toxicity), and infectious (pneumonias, urinary tract infections, and biliary bacteremias).	**Case 34-7 (Questions 1, 2)**

10	Tacrolimus is considered the cornerstone of the immunosuppressant regimen for the vast majority of solid organ transplant recipients. It has complex pharmacokinetics and therefore requires close TDM for optimal use. Tacrolimus is a potent agent that has significantly reduced acute rejection rates; additionally, compared to cyclosporine, tacrolimus has fewer cosmetic side effects (hirsutism, gingival hyperplasia), fewer effects on serum lipoproteins and blood pressure, but has more severe effects on serum glucose levels and more pronounced neurotoxicities.	**Case 34-7 (Questions 3–6)**
11	Acute rejection of the transplanted liver is a common, but usually reversible, consequence after this surgery. It is usually asymptomatic, but can be identified early through serial monitoring of serum transaminases and bilirubin, and definitively diagnosed only through liver biopsy. Treatment usually consists of pulse-dose corticosteroids, followed by a taper, or the use of rabbit antithymocyte globulin for more severe rejections or those refractory to steroid therapy.	**Case 34-7 (Questions 7, 8)**
12	Mycophenolate is considered the adjuvant agent of choice in solid organ transplantation and is used to reduce calcineurin inhibitor exposure or augment immunosuppressant regimen potency. TDM is not common and has yet to prove effective in optimizing therapy. Common side effects with this agent include gastrointestinal issues (nausea, vomiting, and diarrhea) and cytopenias (leukopenia and thrombocytopenia).	**Case 34-7 (Question 9)**
13	Drug interactions with immunosuppressants are numerous and are commonly encountered clinical dilemmas in the transplant recipient. Pharmacists should prospectively screen for these interactions and, depending on their magnitude, may need to prospectively adjust medication regimens. Closer TDM or clinical monitoring is always warranted when adding or removing an interacting medication to a patient on immunosuppression.	**Case 34-8 (Question 1), Table 34-2**
		Case 34-9 (Question 1),

⑭ Infections, including opportunistic infections, are common complications after transplant. Prophylaxis with antimicrobial agents is critical for the most common and severe pathogens. Hepatitis B and hepatitis C are problematic after liver transplant and require immunoprophylaxis or treatment in certain circumstances.	**Table 34-3**
⑮ Cytomegalovirus is the most common and debilitating opportunistic infection after solid organ transplantation. Reactivation or new infection with this virus can lead to severe tissue invasive disease and potentially death. Indirect effects include acute rejection, chronic rejection, graft loss, and potentially, lymphoma. Prophylaxis with potent antivirals (ganciclovir or valganciclovir) is the cornerstone of prevention. Treatment involves a long course of antiviral therapy usually in conjunction with reductions in immunosuppression.	**Case 34-10 (Questions 1–4)**
⑯ Post-transplant lymphoproliferative disorder (PTLD), which is usually a B-cell lymphoma, is the most common cancer encountered after organ transplant. Early PTLD is generally responsive to reductions in immunosuppression; advanced PTLD is usually not responsive to this nor to traditional chemotherapy. The use of rituximab, a monoclonal antibody directed against B cells, has shown promise for treatment of this disease.	**Case 34-11 (Questions 1, 2)**

INTRODUCTION TO TRANSPLANTATION

Solid organ transplantation, adult and pediatrics, is an established therapeutic option for patients with end-stage kidney, liver, heart, and lung disease. For many of these patients, it is the only option. One-year patient and graft survival for these major organs is between 85% and 98%.[1] Pancreas or combined pancreas–kidney transplantation is available as a treatment for diabetic patients with end-stage renal failure.

Unfortunately, many more patients are in need of transplantation than there are organs available. In 2014, about 30,000 organ transplants were performed, whereas 130,000 people were waiting for all organs and 60,000 for kidneys. Consequently, a significant number of candidates die while on the waiting list.

During the 1960s, azathioprine, prednisone, antilymphocyte serum, and antilymphocyte globulin made the success of kidney transplantation possible. In the 1980s, the introduction of cyclosporine had a remarkable impact on solid organ transplantation, and the first monoclonal antibody approved for human use, OKT3, was introduced, but is no longer available.

Since the 1990s, a number of other agents have been approved. These include tacrolimus, mycophenolate mofetil, mycophenolate sodium, sirolimus (formerly rapamycin), and everolimus; monoclonal antibodies, such as basiliximab; a polyclonal antibody, antithymocyte globulin (rabbit antithymocyte globulin); and belatacept. More recently, several agents, such as alemtuzumab, intravenous immunoglobulins (IVIGs), rituximab, eculizumab, and bortezomib, are incorporated into transplant protocols. Several new agents are undergoing investigation.

Although transplantation has a significant positive impact on the quality of life in most patients, rehospitalizations, retransplantation because of graft failure or disease recurrence, donation source (living-related and unrelated organs), and costs to individuals, insurers, and society are major issues. For example, the average Medicare cost during the first year after kidney transplantation is $83,000 and during the second year is $25,000. After liver transplantation, first-year average Medicare cost is $190,000 and second year $30,000.[2] The ability of transplant recipients to pay for their medications or insurance denial or termination of coverage is another major issue.

The goal of immunosuppressive therapy is to prevent organ rejection, prolong graft and patient survival, and improve quality of life. Short-term (i.e., 1–2 years) survival after transplantation has improved dramatically. Long-term survival also has improved, but not to the same degree.[3] As patients live longer after transplantation, the focus of therapy has shifted to survival and management of long-term complications. Immunosuppressive agents are associated with significant long-term complications. These include nephrotoxicity, hypertension, hyperlipidemia, osteoporosis, diabetes, infection and malignancy, as well as graft loss secondary to, recurrence of primary disease, nonadherence and rejection. Many patients also have several pre- and post-transplant comorbidities and complicated drug regimens, which must be evaluated and managed. Pharmacists play an important role in these patient care activities.[4] Although acute rejection rates are significantly lower, this remains a problem, along with chronic rejection and/or chronic allograft injury and long-term outcomes. The search for safer and more effective immunosuppressive regimens continues, along with a better understanding of optimal long-term immunosuppression.[5] This chapter addresses the immunology of transplantation and rejection, indications for kidney and liver transplantation, appropriate use of immunosuppressive agents, and the management of postoperative and long-term complications in these patients. Many of these issues are similar for the various types of solid organ transplantations, but there can also be significant differences as well. This chapter addresses some of these issues as they relate to kidney and liver transplantation.

TRANSPLANTATION IMMUNOLOGY

Successful organ transplantation has evolved from a greater understanding and application of pharmacology, microbiology, molecular and cellular biochemistry and biology, genetics, and immunology. Suppression of the host's immune system and prevention of rejection are vital for host acceptance of the transplanted organ. The ultimate goal is permanent acceptance or tolerance, a situation in which the new organ is seen as "self" by the host's immune system. In general, the currently used immunosuppressive drugs provide a nonpermanent form of tolerance and lifelong immunosuppression is required. A basic understanding of the immune system and the mechanisms of rejection is key to the effective use of immunosuppressive drugs in organ transplantation.

Major Histocompatibility Complex and Human Leukocyte Antigen

The degree to which allogeneic grafting (e.g., donor and recipient from same species) is successful depends on the genetic similarities or differences between the donor organ and the recipient's immune system. The recipient recognizes the transplanted graft as either self or foreign. This recognition is based on the recipient's reaction to alloantigens or antigens (i.e., substances that initiate an immune response that can lead to rejection of the transplanted organ). These substances, also known as histocompatibility antigens, play a very important role in organ transplantation. The ABO blood group system of red blood cells is also important and, in most cases, the donor and recipient should be ABO compatible; otherwise, immediate graft destruction can occur because of antibodies directed against the ABO antigens.

Histocompatibility antigens are glycoproteins that are located on the surface of cell membranes. These are encoded by the major histocompatibility complex (MHC) genes located on the short arm of chromosome 6. In humans, the MHC is called the human leukocyte antigen (HLA). The gene products encoded on the HLA are divided into classes I, II, and III based on their tissue distribution, antigen structure, and function. Class I antigens (HLA-A, HLA-B, and HLA-C) are present on all nucleated cell surfaces and are the primary targets for cytotoxic T-lymphocyte reactions against transplanted cells and tissues. The three class II antigens (HLA-DR, HLA-DQ, HLA-DP) have a more limited distribution and are found on macrophages, B lymphocytes (B cells), monocytes, activated T lymphocytes (T cells), dendritic cells, and some endothelial cells, all of which can act as antigen-presenting cells (APCs). Individual HLA loci are extensively polymorphic. Each transplant recipient possesses two A, B, and DR antigens, one from each parent. This is called a haplotype. Recognition of these polymorphic loci by recipient T cells appears to account for rejection events. Class III antigens (C4, C2, and Bf) are part of the complement system.

Rejection of a transplanted organ is the outcome of the natural response of the immune system, innate and adaptive immunity, to a foreign substance, or antigen, and is a complex process, the understanding of which continues to evolve. This process involves an array of interactions between antigens, T cells, macrophages, cytokines (soluble mediators secreted by lymphocytes, also called lymphokines [the interleukins]), adhesion molecules (also referred to as costimulatory molecules), and membrane proteins expressed on a wide variety of cells that enhance binding of T- and B cells. This process of organ rejection ultimately can involve all elements of the immune response, but it is predominantly T-cell-mediated. This process can be divided into several important steps, which include antigen presentation, T-cell recognition, activation, proliferation, and differentiation of the various components of the immune response. For foreign antigens to interact with recipient T cells and B cells, they must be prepared for presentation by APCs. These APCs usually are recipient macrophages or dendritic cells (indirect pathway of allorecognition), although initially donor cells—dendritic cells or passenger leukocytes and graft endothelial cells—also can serve as APCs (direct pathway of allorecognition). This phase takes place within the blood, lymph nodes, spleen, and the transplanted organ.

Once antigens are prepared and presented, the next step (signal one) involves T-lymphocyte cell recognition of the antigen presented on the surface of the APC. The primary site for this to occur is at the CD3–T-cell receptor (TCR) complex on recipient T cells. This step involves the binding of the antigen, MHC, and TCR for T-cell activation. These T cells also express other molecules (clusters of differentiation [CD]) on their surfaces that, along with CD3, recognize and respond to different types of antigens. These T cells are known as CD4$^+$ cells (T$_H$, helper or inducer T cells) and CD8$^+$ cells (T$_C$, cytotoxic or suppressor T cells). CD4$^+$ cells interact with class II antigens. CD8$^+$ cells interact with class I antigens.

In addition (signal two), proteins known as adhesion molecules or costimulatory molecules promote T-cell signaling and activation. For T-cell activation to occur, binding of these costimulatory molecules as well as binding of the TCR with the presented antigen and MHC is required. Examples of these molecules include

---

intercellular adhesion molecule (ICAM)-1 found on APCs, which bind with lymphocyte function-associated antigen expressed on the surface of T cells; ICAM-1 and ICAM-3 on APCs with CD2 on T cells; B7 (now called CD80 and CD86) on APCs with either CD28 or CTLA4 on T cells; and CD40 on APC with CD40 ligand (now called CD154) on T cells. The binding of costimulatory molecules is critical to T-cell activation. Without this costimulation, T cells undergo abortive activation or programmed T-cell death (apoptosis).

Once recognition and costimulatory binding occurs, T-cell activation and proliferation are initiated. After interacting with class II antigens and stimulation from IL-1 secreted from macrophages, T$_H$ cells produce and secrete cytokines (e.g., interleukin [IL]-2 and interferon [INF]-γ). T$_H$ cells are classified according to their cytokine-secretion pattern into either T_{H1} or T_{H2} cells. T_{H1} cells secrete IL-2, INF, and tumor necrosis factor (TNF), which stimulate cytotoxic T cells (T_C). T_{H2} cells secrete IL-4, IL-5, IL-6, IL-10, and IL-13, which stimulate B-cells. T_H cells, along with T_C cells, are stimulated to express cell-surface IL-2 receptors (IL-2R) and other cytokines. Once the T_C cells express IL-2R, they bind to IL-2 and other cytokines, which leads to signal transduction that results in proliferation, division, and stimulation of T cells (signal 3). These committed T_C cells bind directly to allogeneic cells and produce cell lysis. T_H-secreted cytokines recruit other T cells, which results in further cytotoxicity. During this process, T_H cells also produce cytokines that trigger a cascade of events involving B cells and antibody production, complement fixation, increased macrophage infiltration, neutrophil involvement, fibrin deposition, platelet activation and release, prostaglandin release, and inflammatory response at the graft site. These delayed-type hypersensitivity and humoral responses occur in conjunction with one another and are not mutually exclusive. This results in cellular and tissue injury and graft destruction

The antibodies produced by plasma cells, which are transformed B cells under the influence of cytokines, bind to the target antigenic cells. This leads to local deposition of complement and results in immune complexation and injury to the graft (complement-mediated cell lysis). The newly formed antibodies cause a series of interactions to occur with T cells, which lead to cytotoxicity (antibody-dependent, cell-mediated cytotoxicity). These cell-mediated and humoral immunologic events can impair organ function so significantly that without therapeutic intervention, complete organ graft dysfunction may occur. Under certain circumstances, which are not clear, certain T_C cells, known as suppressor T cells, downregulate the immune response to alloantigen.[6]

Human Leukocyte Antigen Typing

The genetic compatibility between donor and recipient can have a major impact on acute rejection, graft function, graft survival, and patient survival. For example, in kidney transplantation, the closer the HLA matching is between recipient and donor, the better the outcome, particularly over the long term. To determine this compatibility, a number of laboratory tests, including serologic, flow cytometric, genetic-DNA-based, and cellular assessments of donor and recipient serum and lymphocytes, are performed before organ transplantation. This process is referred to as tissue typing. Lymphocytes are typed for HLA-A, HLA-B, and HLA-DR. Typing for HLA is performed using the donor and recipient lymphocytes for serology-based techniques or tissue or fluid containing nucleated cells.[7]

The panel-reactive antibody (PRA) test is commonly used to assess organ compatibility because recipients may have HLA antibodies from previous exposure to antigenic stimuli (e.g., blood transfusions, previous transplantation, and pregnancy). In this test, the recipient's serum is tested against a cell panel of known HLA specificities that are representative of possible donors in the general population. The percentage of cell reactions (recipient with potential donor) determines a recipient's PRA. It is done periodically on patients on the waiting list to determine their immunologic reactivity. The potential recipient with a higher percentage of PRA (>20%–50%) is at higher risk for rejection and will generally a have longer wait time for a kidney than patients with PRA less than 20%. With recent changes (December 2014) to kidney allocation systems, this wait time may change for these patients.

A cytotoxic and/or flow cytometry lymphocyte cross-match is also performed prior to transplantation. In this case, the potential recipient's serum is cross-matched to determine whether preformed antibodies to the donor's lymphocytes are present. A positive cross-match indicates the presence of recipient cytotoxic IgG antibodies to the donor. In kidney transplantation, a positive cross-match is usually considered a contraindication. Recently, a number of transplant programs have utilized desensitization strategies to reduce the level of HLA antibodies present in potential recipients as a mechanism to reduce likelihood of a positive cross-match with either identified living donors or future potential deceased donors. Common strategies to reduce these preformed HLA antibodies include serial delivery of plasmapheresis coupled with IVIG, rituximab, and bortezomib.[8] In liver transplantation, a positive cross-match is not an absolute contraindication because the need is urgent and because the liver appears to be more resistant immunologically to this type of reaction. These liver transplant recipients can, however, experience significant complications and early graft dysfunction. In kidney transplantation, organ allocation and matching now utilize a virtual cross-match in which potential recipients are listed with known unacceptable HLA antigens (those that have been pre-identified in the patient). If a potential donor is identified with a specific HLA antigen that the recipient has known antibodies directed against, they will be skipped on the list.

ABO blood typing is one of the most critical of all evaluations when determining the genetic compatibility for all solid organ transplants. Transplantation of an organ with ABO incompatibility typically results in a hyperacute rejection and destruction of the graft, although in kidney transplant, newer therapeutic approaches to overcome ABO incompatibility have been successful.[7]

IMMUNOSUPPRESSIVE AGENTS

Immunosuppressives, based on an improved understanding of their mechanisms of action and the mechanisms of rejection, have had the most significant impact on patient and graft survival. The currently used immunosuppressives are shown in Table 34-1. These agents can be categorized as induction or maintenance therapy.[9] Sites of action and role of the currently used agents are discussed below.

MAINTENANCE

Azathioprine

Azathioprine is a prodrug of 6-mercaptopurine (6-MP). Azathioprine and 6-MP are purine antagonist antimetabolites. The introduction of cyclosporine, tacrolimus, mycophenolate, and sirolimus has led to a significant reduction of azathioprine use or its elimination altogether in immunosuppressive protocols. It can be useful in some cases, because it is inexpensive, or in patients who cannot tolerate other agents. It continues to be used in other countries.[9]

Table 34-1

Currently Used Immunosuppressive Agents

Drug (Brand Name)	Usual Dose/Route (How Supplied)	Therapeutic Use(s)	Major Adverse Effects
Alemtuzumab (Campath-H1)	IV 0.3 mg/kg or 30 mg × 1 dose (30-mg vial for injection)	Prevention and treatment of acute cellular and antibody-mediated rejection; steroid-free protocols	Lymphopenia, leukopenia, infection
Azathioprine (Imuran)[a]	IV or Oral 1–3 mg/kg/day (50-mg tablet; 100-mg vial for injection)	As maintenance agent to prevent acute rejection	Leukopenia, thrombocytopenia, hepatotoxicity, nausea and vomiting, diarrhea, pancreatitis, infection
Antithymocyte globulin, equine (Atgam)	IV 10–20 mg/kg/day (250 mg/5 mL ampule for injection)	Treat acute rejection (including severe or steroid-resistant forms); as induction agent in high-risk patient to prevent acute rejection	Anemia, leukopenia, thrombocytopenia, arthralgia, myalgias, nausea and vomiting, diarrhea, fevers, chills, hypotension, tachycardia, anaphylaxis, infection
Antithymocyte globulin, rabbit (Thymoglobulin)	IV 1.5 mg/kg/day given daily for 4–10 days (25 mg/5 mL vial for injection)	Treat acute rejection (including severe or steroid-resistant forms); as induction agent in high-risk patient to prevent acute rejection	Fever, chills, nausea and vomiting, hypotension, neutropenia, flushing, rash, itching, joint pain, myalgias, thrombocytopenia, infection
Basiliximab (Simulect)	IV 20 mg × 2 doses 10 mg; 2 doses for children if <35 kg (10- and 20-mg vial for injection)	As induction agent to prevent acute rejection	Abdominal pain, dizziness, insomnia, hypersensitivity reaction (rare)

Belatacept (Nulojix)	IV Initial Maintenance: 10 mg/kg on days 0, 4, 14, 28 and week 8 and12 and monthly thereafter Conversion from CNI: 5 mg/kg q 2 weeks for 5 doses, then every 4 weeks thereafter	As maintenance agent to prevent acute rejection; conversion agent from CNIs in patients with intolerances.	Anemia, neutropenia, diarrhea, UTIs, headaches, peripheral edema, PTLD
Cyclosporine[a] (Sandimmune)	Oral 5–10 mg/kg/dose BID IV 1.5–2.5 mg/kg/dose (100 mg/mL oral solution; 25- and 100-mg capsule; 250 mg/5 mL ampule for injection)	As maintenance agent to prevent acute rejection	Nephrotoxicity, hypertension, neurotoxicity, hair growth, gingival hyperplasia, hyperglycemia, hyperkalemia, dyslipidemia, hypomagnesemia, infection, neoplasm
Cyclosporine (Neoral, Gengraf, various others)[a]	Oral 4–8 mg/kg/day BID (100-mg solution; 25-, 50-, and 100-mg capsule)	As maintenance agent to prevent acute rejection; conversion agent from tacrolimus in patients with intolerance	Same as above
Everolimus (Zortress)	Oral 0.5–1.5 mg BID (0.25-, 0.5-, 0.75-mg tablets	As maintenance agent to prevent acute rejection; conversion agent from CNI in patients with intolerance or poor response	Dyslipidemia, thrombocytopenia, neutropenia, impaired healing, mouth ulcers, proteinuria, pneumonitis (rare)
Methylprednisolone[a] sodium succinate (Solu-Medrol, various others)	10–1,000 mg/dose (40-, 125-, 250-, 500, 1,000-, and 2,000-mg vial for injection)	As induction and maintenance agent to prevent acute rejection; to treat acute rejection	Hyperglycemia, psychosis, euphoria, impaired wound healing, osteoporosis, acne, peptic ulcers, gastritis, fluid, electrolyte disturbances, hypertension, dyslipidemia, leukocytosis, cataracts, cushingoid state, infection, insomnia, irritability
Mycophenolate[a] mofetil (CellCept)	1.5–3.0 g/day BID IV/PO (250-mg capsule; 500-mg tablet; 200 mg/mL oral suspension; 500-mg vial for injection)	As maintenance agent to prevent acute rejection; conversion agent from azathioprine and sirolimus in patients with intolerance or poor response	Diarrhea, nausea and vomiting, neutropenia, dyspepsia, ulcers, infection, thrombocytopenia, anemia
Mycophenolate[a] sodium (Myfortic)	360–720 mg PO BID (180- and 360-mg tablets)	As maintenance agent to prevent acute rejection. Alternative to MMF	Similar side effect profile as MMF

Prednisone[a]	Oral 5–20 mg/day (1-, 2.5-, 5-, 10-, 20-, 50-, and 100-mg tablet)	As maintenance agent to prevent acute rejection	See methylprednisolone
Sirolimus[a] (Rapamune)	Oral 2–10 mg/day (0.5-, 1-, and 2-mg tablet; 1 mg/mL oral solution)	As maintenance agent to prevent acute rejection; conversion agent from CNI or mycophenolate or azathioprine in patients with intolerance or poor response	Dyslipidemia, thrombocytopenia, neutropenia, anemia, diarrhea, impaired healing, mouth ulcers, proteinuria, pneumonitis (rare)
Tacrolimus (Prograf, Astagraf XL, Envarsus XR)[a]	Oral 0.15–0.3 mg/kg/day BID IV 0.025–0.05 mg/kg/day as continuous infusion (0.5-mg, 1-mg, and 5-mg capsule; 5 mg/mL ampule for injection) Astagraf XL: Oral 0.1–0.2 mg/kg/day Once daily (0.5-mg, 1-mg, and 5-mg capsules) Envarsus XR: Oral 0.1–0.2 mg/kg/day once daily 80% of total daily dose of tacrolimus when converting from immediate-release formulation (0.75-, 1-, and 4-mg tablets)	As maintenance agent to prevent acute rejection; conversion agent from cyclosporine in patients with intolerance or poor response	Nephrotoxicity, hypertension, neurotoxicity, alopecia, hyperglycemia, hyperkalemia, dyslipidemia, hypomagnesemia, infection, neoplasm
Bortezomib (Velcade)	1.3 mg/m^2 on days 1,4, 8, and 11 IV bolus or sc (3.5 mg single use vial)	Inhibits plasma cells	Bone marrow suppression, thrombocytopenia, neuropathy, hypotension, gastrointestinal
Eculizumab (Soliris)	600–1,200 mg IV infusion (300 mg single use vial [30 mL of 10 mg/mL soln])	Inhibits complement	Infusion reaction, headache, hypertension, leukopenia, infections
Rituximab (Rituxan)	375 mg/m^2 × 1–5 doses or 500 mg/m^2 single-dose IV infusion (100 and 500 mg single use vial, in 10 mg/mL concentration)	Inhibits B-cell production	Infusion reactions (fever, chills, rigors); pain at infusion site, infections
Intravenous Immunoglobulin (Carimune NF, Flebogamma, Gammagard S/D, Gamunex, Iveegam EN, Octagam, Polygam)	100 mg/kg–2 g/kg IV infusion (vial size varies based on manufacturer, ranging from 1, 2.5, 5, 6, 10, 12, 20, 30 and 40 g; usually concentrations are	Immunomodulation of T- and B cells and/or immunoglobulin replacement	Infusion reactions (fever, chills, rigors); pain at infusion site, thrombosis, hemolytic anemia, acute renal failure, septic meningitis

	5% and 10%)		

[a] Generic products available.

BID, 2 times daily; CNI, calcineurin inhibitor; IV, intravenous; MMF, mycophenolate mofetil; PO, orally.

Azathioprine, a nonspecific antimetabolite immunosuppressive agent, affects both cell-mediated (i.e., T cell) and antibody-mediated (i.e., B cell) immune responses. Because it inhibits the early stages of cell differentiation and proliferation, azathioprine is useful for preventing rejection, but it is ineffective for the treatment of acute rejection. 6-MP, an active metabolite, is incorporated into DNA and RNA, thereby interfering with the intracellular formation of thioguanine nucleotides (TGN). 6-MP is intracellularly converted by hypoxanthine phosphoribosyltransferase to thioinosinic acid and then to thioguanine nucleotides. 6-MP may have two separate immunosuppressive effects: inhibition of cellular proliferation and cytotoxicity. A decrease in the levels of intracellular purine ribonucleotides decreases cellular proliferation, and incorporation of TGN into DNA mediates cytotoxicity.

The major metabolic conversion of azathioprine to 6-MP is via nucleophilic attack by glutathione. The liver and red blood cells are thought to be major tissue sites for this metabolic conversion. The 6-MP formed by this reaction can be metabolized further to thiopurine ribonucleosides and ribonucleotides such as 6-thioguanine nucleotide. These active metabolites, which have longer half-lives, are responsible for immunosuppressive activity. Azathioprine pharmacokinetics are not affected by renal dysfunction, but 6-TGN metabolite concentrations can accumulate in this situation.[1]

The most common adverse effect of azathioprine is bone marrow suppression. Bone marrow suppression may be related to a genetic deficiency of the enzyme, thiopurine methyltransferase. Low activity of this enzyme is rare but in some individuals it

leads to greater availability of 6-MP, elevated 6-thioguanine levels, and susceptibility to myelosuppression. Low levels of thiopurine methyltransferase and specific genetic polymorphisms of this enzyme have been associated with severe azathioprine myelotoxicity and reduced efficacy.[10,11] Testing for this polymorphism has been advocated. However, few transplant centers perform genetic testing prior to use.

Mycophenolate Mofetil and Mycophenolate Sodium

As a result of several multicenter comparative registry trials in kidney transplant recipients, mycophenolate mofetil (MMF) has replaced azathioprine in many transplant protocols. MMF is used as adjunctive therapy in combination with cyclosporine or tacrolimus, prednisone, mammalian target of rapamycin (mTOR) inhibitors, and monoclonal and polyclonal antibodies to prevent acute rejection and used for calcineurin inhibitor (CNI) withdrawal and minimization. It is also used as rescue therapy when patients have not responded to, or cannot tolerate, the side effects of other immunosuppressive agents.

MMF is an antiproliferative antimetabolite that inhibits purine synthesis, but in a more selective manner than azathioprine. Unlike azathioprine, MMF interferes with the de novo pathway for purine synthesis. MMF is the morpholinoethyl ester prodrug of mycophenolic acid (MPA), which is the active component. MPA selectively, noncompetitively, and reversibly blocks an enzyme known as inosine monophosphate dehydrogenase (IMPDH) found primarily in actively proliferating T- and B cells. T- and B cells rely on this enzyme and the de novo purine pathway to produce purine nucleotides for DNA and RNA synthesis. Thus, MPA interferes with T-cell and B-cell proliferation. It is more selective than azathioprine. MPA also may affect cytokine production. Other secondary effects include inhibition of B-lymphocyte antibody production, decreased adhesion molecule expression, decreased smooth muscle proliferation and recruitment, and infiltration of neutrophils[12] (MMF pharmacokinetics are complex and discussed in detail in Case 34-7, Question 9).

Another oral formulation of MPA, enteric-coated mycophenolate sodium, is also approved by the US Food and Drug Administration (FDA) to prevent rejection in kidney transplantation, when used in combination with a calcineurin inhibitor (CNI) and corticosteroids. The original purpose of designing the enteric-coated formulation was to reduce or prevent the gastrointestinal (GI) side effects commonly seen with MMF. However, most data suggest that the efficacy rates and side effect profiles of MMF and mycophenolate sodium are nearly identical. These two agents are not bioequivalent.[12] Other aspects of their use, generic products, therapeutic drug monitoring, and adverse effects will be addressed later in this chapter (Case 34-7, Question 9).

Corticosteroids

Prednisone, methylprednisolone, and prednisolone—all synthetic analogs of hydrocortisone—are the primary corticosteroids used to prevent and treat rejection of transplanted organs. These agents usually are given in fixed doses or dosing is based on body weight (mg/kg) despite the pharmacokinetic differences. Although they are an important part of immunosuppression, a goal of most transplantation programs is to minimize, eliminate, or avoid corticosteroid use because of their numerous and significant side effects.

Corticosteroids have multiple effects on most cells and tissues of the body, but it is their anti-inflammatory and, more importantly, their immunosuppressive properties that serve as the basis for their use in organ transplant recipients. The corticosteroids bind with specific intracellular glucocorticoid receptors and interfere with RNA and

DNA synthesis as well as transcription of specific genes. Cell function is altered, resulting in suppression or activation of gene transcription. Corticosteroids also affect RNA translation, protein synthesis, cytokine production and secretion, and protein and cytokine receptor expression.

Even after a single dose, corticosteroids cause marked lymphocytopenia by redistribution of circulating lymphocytes to other lymphoid tissues, such as the bone marrow, rather than by cell lysis; however, they also transiently increase the number of peripherally circulating neutrophils. Corticosteroids inhibit IL-1 and IL-6 production from APC, a number of events associated with T-cell activation, and IL-2 and IFN-γ production. They interfere with the action of IL-2 and IL-2R on activated T cells, resulting in the inhibition of T_{H1} function. They can enhance IL-10 regulatory function and enhance T_{H2} cell function. Moderate-dose to high-dose corticosteroids also inhibit cytotoxic T-cell function by inhibiting cytokine production and lysis of T cells. They can inhibit early proliferation of B cells but have a minimal effect on activated B cells and immunoglobulin-secreting plasma cells. The corticosteroids affect most cells and substances associated with acute allograft rejection and inflammatory reactions. They inhibit accumulation of leukocytes at sites of inflammation; inhibit macrophage functions, including migration and phagocytosis; inhibit expression of class II MHC antigens induced by INF-γ; block release of IL-1, IL-6, and TNF; inhibit the upregulation and expression of costimulatory molecules and neutrophil adhesion to endothelial cells; inhibit secretion of complement protein C3; inhibit phospholipase A_2 activity; and decrease production of prostaglandins.[13]

Calcineurin Inhibitors

CYCLOSPORINE

The activity of cyclosporine is mediated through a reversible inhibition of T-cell function, particularly T_H cells. Its major effect is inhibiting the production of IL-2 and other cytokines, including INF-γ. These actions result in an inhibition of the early events of T-cell activation, sensitization, and proliferation. Cyclosporine has little effect on activated mature cytotoxic T cells. Therefore, it has little usefulness in the treatment of acute rejection. Its site of action is within the cytoplasm of T cells after antigenic recognition and signaling occurs. Cyclosporine binds to an intracellular protein (immunophilin) called cyclophilin. Although binding to cyclophilin is required, it alone is not sufficient for immunosuppression. This cyclosporine–cyclophilin complex then binds to a protein phosphatase, calcineurin. This is thought to prevent activation of nuclear factors involved in the gene transcription for IL-2 and other cytokines, including IFN. Also, because of this inhibition, cyclosporine indirectly impairs the activity of other cells, macrophages, monocytes, and B cells in the immune response. Cyclosporine has no effect on hematopoietic cells or neutrophils. Cyclosporine is metabolized extensively in the liver to more than 25 metabolites. Two of these metabolites elicit a lower immunosuppressive effect in vitro. The role of these metabolites in the development of toxicity with cyclosporine is unclear.[14] The pharmacokinetics, dosing, and therapeutic drug monitoring (TDM) of cyclosporine are described in Case 34-3, Question 1 and Case 34-4.

TACROLIMUS

Tacrolimus is a macrolide with a different molecular structure than cyclosporine. Tacrolimus is more effective than cyclosporine in liver and kidney transplant recipients as the primary immunosuppressant in combination with corticosteroids or mycophenolate, azathioprine, mTOR inhibitors, and antibodies. It also is effective in some patients as rescue treatment in liver and kidney recipients experiencing acute or chronic rejection resulting from failure of standard immunosuppressive therapy. Tacrolimus is the preferred CNI over cyclosporine in most transplant centers.[2]

The activity of tacrolimus is similar to that of cyclosporine, but the concentrations of tacrolimus needed to inhibit production of IL-2 are 10 to 100 times lower than those of cyclosporine. Tacrolimus also inhibits production of other cytokines, including IL-3, IL-4, and INF-γ, TNF, and granulocyte-macrophage colony-stimulating factor. It has variable effects on B-cell response and also has anti-inflammatory effects. As with cyclosporine, tacrolimus binds to an intracellular, although different, protein: FK binding protein 12. This protein, which interacts with calcineurin, inhibits gene transcription of cytokines and interferes with T-cell activation.[15] The pharmacokinetics, dosing, and TDM of tacrolimus are described in Case 34-7, Question 3-6.

mTOR Inhibitors

Sirolimus, formerly known as rapamycin, is an FDA-approved agent for prevention of acute rejection and for withdrawal of cyclosporine in kidney transplantation. Positive results for sirolimus also have been observed in other transplant populations; in situations in which it is used in combination with other agents, including antibodies, tacrolimus, mycophenolate and prednisone; and when it has been used for rescue therapy. Its major use is in CNI avoidance, withdrawal, or minimization protocols.

Unlike CNIs, which work earlier in the T-cell activation cycle and inhibit cytokine production, sirolimus is an inhibitor of late T-cell activation. It does not block cytokine production; rather, it inhibits signal transduction, which blocks the response of T cells and B cells to cytokines, such as IL-2. Sirolimus binds to the same immunophilin bound by tacrolimus, FK binding protein. This complex interferes with the action of certain enzymes or proteins involved in cell proliferation signaling. Both cyclosporine and tacrolimus inhibit calcineurin, whereas sirolimus influences a protein called the mammalian target of rapamycin (mTOR). Sirolimus also inhibits an enzyme called P7056 protein kinase, which is involved in microsomal protein synthesis. These effects result in cell-cycle arrest, blockage of messenger RNA production, and blockage of cell proliferation. Sirolimus also inhibits proliferation of smooth muscle cells and may, although it is too early to tell, reduce the development of chronic rejection and, potentially, cancer.

Sirolimus exhibits significant pharmacokinetic variability. Its average bioavailability is 15%; C_{max} and AUC are linear over a wide range of doses. Sirolimus is extensively distributed. It distributes primarily into red blood cells and is highly plasma protein-bound, approximately 92%. It also binds to lipoproteins. Sirolimus is extensively metabolized in the gut and liver by cytochrome P-450 3A4 isoenzymes, and it is a substrate for P-glycoprotein. Its drug interaction profile is similar to that of cyclosporine and tacrolimus. Renal elimination accounts for 2% of a dose. The terminal half-life is approximately 57 to 63 hours and the time to steady state is 10 to 14 days in adults and shorter in children.

Everolimus is the newest FDA-approved mTOR inhibitor for use in both kidney and liver transplantation. Its mechanism of action is similar to sirolimus. Like sirolimus, it is used in CNI avoidance, withdrawal, or minimization protocols.

Everolimus is hepatically metabolized through the cytochrome P-450 3A4 but has a shorter half-life, average 30 hours, and different dose and frequency schedule than sirolimus. Similar to sirolimus, it requires monitoring of trough blood concentrations, although the target range is different from sirolimus. Its role in transplantation is generally similar to sirolimus, but direct comparison to sirolimus is needed.[16] Aspects of its use are discussed in Case 34-4, Question 2.

Belatacept

This agent is the first FDA-approved intravenous (IV) maintenance agent. Belatacept is a CTL4-Ig, which blocks the costimulatory pathway of CD28 or CTL-A4:CD80/CD86 binding interactions. CTLA4-Ig binds to CD80/CD86 to a greater degree than CD28, resulting in inhibition of costimulation and T-cell activation. Belatacept is given once every few weeks in combination with other agents, such as mycophenolate and prednisone, and generally well tolerated. It has been used as initial therapy, or for CNI avoidance or withdrawal (conversion) to reduce development or progression of CNI-induced reduction in renal function. Benefits on renal function have been demonstrated as well as other CNI-associated adverse effects. However, it should be noted that there is an increased risk of acute rejection, when belatacept is used in combination with mycophenolate, as compared to a cyclosporine- and mycophenolate-based regimen. There are no large-scale studies comparing it to tacrolimus-based regimens or in combination with cytolytic induction therapy. In clinical practice, some transplant centers utilize belatacept as a conversion agent in patients that cannot tolerate CNIs. There is an ongoing multicenter study to assess the efficacy of this. Other small studies have been published that utilize belatacept with mTOR therapy. It should be noted that belatacept is contraindicated in patients who are EBV antibody negative, due to risk of post-transplant lymphoproliferative disorder (PTLD). The phase III studies that demonstrated a higher risk of PTLD in those that received belatacept noted this was only the case in EBV-naive recipients, and CNS PTLD was of particular concern. Recent data presented in abstract form, which followed patients from the phase III studies out for greater than 7 years post-transplant, have now demonstrated improved graft survival in the belatacept arm, as compared to the cyclosporine group. Thus, this agent may offer beneficial outcomes for certain low-risk kidney transplant recipients. Use in other organs, particularly liver transplant recipients, is not recommended, due to previous studies demonstrating inferior outcomes, as compared to CNI-based therapy.[17]

INDUCTION

Polyclonal Antibodies

ANTITHYMOCYTE GLOBULINS

Polyclonal antibody products have been used for decades to prevent and treat acute rejection. Polyclonal products used today are administered IV and include equine (lymphoglobulin) and rabbit antithymocyte globulin, which is considered the polyclonal antibody of choice.

Antithymocyte globulin (ATG) preparations have also been made in goats and sheep for investigational study. However, the following discussion is limited to the products produced in horses and rabbits. Regardless of the species from which they are produced, all ATG products have similar pharmacologic effects. Their potency and antibody specificity vary, however, from batch to batch and between products. The production of polyclonal equine or rabbit antibody begins with the injection of homogenized human spleen or thymus preparations into the animals. This injection induces an immune response in the animals directed against human T lymphocytes; serum containing antibodies to T cells is collected from the animals and purified. Other antibodies to human cells are produced as well, however. These antibodies bind to all normal blood mononuclear cells in addition to T lymphocytes and B lymphocytes, resulting in depletion of lymphocytes, platelets, and leukocytes from the peripheral circulation. The mechanism of action of these agents is thought to be linked to lysis of peripheral lymphocytes, uptake of lymphocytes by the reticuloendothelial system, masking of lymphocyte receptors, apoptosis, and immunomodulation. These agents contain antibodies to a number of cell-surface markers on lymphocytes, including CD2, CD3, CD4, CD8, CD11a, CD25, CD44, CD45, HLA-DR, and HLA class I antigens. They also interfere with leukocyte adhesion and trafficking and also have effects against $CD20^+$ B cells. ATG preparations can produce a rapid and profound depletion of circulating T cells, often within 24 hours of the initial dose. The duration of the effect can last several weeks after a course of therapy, particularly with rabbit antithymocyte globulin. Antibodies can be produced to these products as well. This, however, does not appear to influence clinical outcomes (see Case 34-1).[18]

Monoclonal Antibodies

BASILIXIMAB

Basiliximab is an IL-2R antagonist, monoclonal antibody approved for use in combination with other immunosuppressives to prevent acute cellular rejection in kidney transplantation. Basiliximab is a chimeric antibody that contains both murine and human antibody sequences. This agent prevents episodes of acute rejection in kidney transplant recipients. It has been used, although not as frequently, in liver transplants. Comparative studies between basiliximab and other antibodies, such as rabbit antithymocyte globulin, have been conducted. Advantages over these other agents include ease of administration, minimal side effects, low immunogenicity, no greater infections or malignancy rates, and fewer required doses. It is well tolerated, although there are rare reports of anaphylaxis. Basiliximab appears to be most effective in immunologically low-risk patients, whereas in high-risk patients, its use may be limited. It binds to the α-subunit of the IL-2R, also known as CD25 or the TAC subunit, which is expressed only on the surface of activated T cells; this subunit is critical to IL-2 activation of T cells in the acute rejection process. Basiliximab prevents the IL-2R from binding with IL-2, thereby blocking T-cell activation. It does not cause lymphocyte depletion. Basiliximab, with the two-dose IV regimen, on days 0 and 4 post-transplant, saturates the receptor for approximately 30 to 50 days in kidney transplants.[19] See Case 34-1, Question 4.

ALEMTUZUMAB

Alemtuzumab is a humanized monoclonal antibody against CD52 proteins on the surface of T cells and B cells, natural killer cells, macrophages, and granulocytes. Binding of CD52 elicits antibody-dependent lysis of these cells. It is approved for use in certain types of leukemias, but not in organ transplant. Because it causes a profound reduction or depletion in lymphocytes, especially T_H lymphocytes, a number of studies have evaluated its effect as induction therapy to prevent acute rejection after kidney transplant. Several studies have investigated its use in low and high immunologic risk transplants and in steroid avoidance or withdrawal regimens and CNI avoidance or withdrawal regimens. Short-term studies have indicated a role for this agent in these situations. It is rarely used in liver transplantation. Most protocols with this agent give a single IV or subcutaneous (SC) dose in the operating room. With this dose, significant neutropenia and lymphopenia can occur, lasting for months to years in some patients. This single-dose regimen has been successful in reducing the incidence of fungal and viral infections as compared with multiple-dose regimens although infection is still a concern with single dose.[20,21] See Case 34-1, Question 4.

OTHER AGENTS

These agents, although not indicated for kidney transplantation, are being used and studied primarily in kidney transplantation. Intravenous immunoglobulin and rituximab, an anti-B-cell CD20 monoclonal antibody, are being used pre- and post-transplant in order to transplant patients with ABO incompatibility or who are highly sensitized. Eculizumab, a C5 complement inhibitor, and bortezomib, a proteasome inhibitor, are also being used and studied in these situations, as well as for the treatment of antibody-mediated acute cellular rejection.[22,23]

KIDNEY TRANSPLANTATION

Indications and Evaluation

All patients with ESRD are potential candidates for kidney transplantation unless contraindicated. The contraindications (absolute or relative) are determined by the individual transplant center. Absolute contraindications include current malignancy, active infection, active liver disease, HbsAg-positive, severe or symptomatic cardiac or pulmonary disease, specific renal diseases with an accelerated recurrence rate, substance abuse, and abnormal psychosocial and noncompliant behavior. Relative contraindications for the recipient of a kidney transplant include chronic liver disease, active infection, positive for hepatitis C, human immunodeficiency virus (HIV) positive, morbid obesity, current positive cross-match, and age greater than 70 years. The relative contraindication for the elderly with ESRD is controversial because approximately 40% of the ESRD population is older than 65 years and an increasing number of these patients are undergoing kidney transplantation. Patients with ESRD need not wait until they are receiving dialysis before being considered for a kidney transplant because early transplantation is associated with lower cost, better quality of life, and longer survival than patients on dialysis awaiting transplantation. The primary diseases leading to ESRD and transplant are diabetes, hypertension, glomerulonephritis, and polycystic kidney disease.

Diabetes and hypertension are the most likely causes of ESRD. A kidney transplant should return renal function to near normal (i.e., a glomerular filtration rate between 50 and 80 mL/minute), improve quality of life, and correct the complications of ESRD such as anemia, hypocalcemia, and hyperphosphatemia, but not diabetes, hypertension, or hyperlipidemia.

The risk–benefit ratio must be considered when evaluating a patient for any organ transplantation. In general, kidney transplants are performed to improve the quality of life and avoid the complications and outcomes associated with dialysis and renal failure. It is also more cost effective than dialysis. On the other hand, patients who are candidates for liver transplantation will die if the transplanted liver fails. Therefore, the criteria established for organ transplantation must be evaluated carefully before it is offered to any patient.

Donor and Recipient Matching

HLA matching of donor and recipient at the HLA-A, HLA-B, and HLA-DR loci is associated with better graft survival and longer half-lives for both living-related and deceased donor kidney transplants. A six-antigen match is ideal, whereas a zero antigen match is less favorable. The half-life refers to the time it takes for half of the grafts that survive the first year to fail. Organ half-lives are longer with living donors (average 15.9 years) compared with deceased donors (average 11.9 years).[24] For kidney recipients, the 1- and 3-year graft survival for a first deceased donor transplant is greater than 90% and greater than 80%, respectively. These

---

positive factors may be offset, however, by ethnicity. Patient and graft survival after kidney transplantation is reduced in the African-American population compared with others because of immunologic, medical, pharmacologic, pharmacokinetic, pharmacogenomic, and socioeconomic reasons. Along with African-American race, other risk factors associated with decreased survival include advanced donor age, recipient age less than 15 years and greater than 50 years, retransplantation, a high PRA (>20%–50%), and delayed graft function. Recipients who fall into these categories are referred to as high-risk patients.

Because of a limited number of donors, the organ transplant community has devised methods to increase the donor pool by attempting to safely utilize marginal donors. In its most current form, this allocation system has incorporated the use of a predictive tool that determines the degree of marginality, termed the Kidney Donor Profile Index (KDPI). The KDPI uses donor information, including age, height, weight, ethnicity, hypertension, diabetes, cause of death, serum creatinine, hepatitis C status, and circulatory death status to rate kidneys from 0% to 100%. Those in the higher percentile are more likely to fail, as compared to kidneys with lower KDPIs. In the current allocation system, donors with a high KDPI (85% or higher) are reserved for older recipients.[25]

Immunosuppressive Therapy

CASE 34-1

QUESTION 1: G.P. is a 52-year-old, 72-kg African-American man with end-stage renal disease (ESRD) secondary to type 2 diabetes mellitus, hypertension, and hyperlipidemia. He has been undergoing hemodialysis 3 times a week for 4 years. Other medical problems include anemia, hypocalcemia, and hyperphosphatemia. G.P.'s medications include amlodipine 10 mg daily, ramipril 10 mg twice daily (BID), Lipitor 20 mg daily, calcium carbonate two tablets with meals and at bedtime, sevelamer 800 mg with meals, glargine insulin 30 units daily, Novolog 8 units with meals, and erythropoietin 8,000 IU IV 3 times weekly. He has been on the kidney transplant waiting list for 2 years. He is called by the transplant coordinator and admitted for a possible deceased donor (formerly called cadaveric) kidney transplant. G.P. has the same blood type as the donor. His most recent cPRA is 10%. Cross-match is negative, and HLA typing reveals a three-antigen match (A1, A2, and B35) between donor and recipient. On admission to the hospital, his laboratory values are as follows:

Na, 141 mEq/L
Potassium (K), 4.7 mEq/L
Cl, 102 mEq/L
Bicarbonate (Hco_3), 23 mEq/L
Blood urea nitrogen (BUN), 44 mg/dL
Serum creatinine (SCr), 13.9 mg/dL
Calcium (Ca), 7.8 mEq/L
Phosphorus, 6.2 mg/dL
Glucose, 225 mg/dL
Albumin 3.5 g/dl
WBC count, 8.4 cells/mL
Hemoglobin (Hgb), 10.8 g/dL
Hematocrit (Hct), 32%

His serology is negative for HIV, hepatitis B surface antigen (HbsAg), hepatitis C, and cytomegalovirus (CMV), and is positive for antibody to the surface antigen of hepatitis B (anti-Hbs), positive for Epstein–Barr virus (EBV) antibody

Before the transplant procedure, G.P. receives MMF 1 g orally (PO) and cefazolin 1 g IV. During surgery, just before reperfusion of his new kidney, he received methylprednisolone 500 mg IV and rabbit antithymocyte globulin 100 mg IV. He is also given furosemide 100 mg IV after the kidney has been transplanted. Methylprednisolone 250 mg IV is to be given on the day after surgery. The methylprednisolone dose is to be decreased to 100 mg IV on the second postoperative day for one dose. Prednisone 60 mg (1 mg/kg/day) PO is to be given on the subsequent day for one dose and tapered by 0.3 mg/kg/day to 20 mg daily by day 7 after surgery and further tapered to 5 mg daily within a month. Tacrolimus nasogastric (NG) or PO 0.1 mg/kg/day or 3 mg every 12 hours will be started within 12 hours after surgery if renal function improves. The dosage will be adjusted according to tacrolimus whole blood trough concentrations. MMF will be continued at 1 g PO BID. He will also continue with antibody induction with rabbit antithymocyte globulin 100 mg IV on days 1, 2, 3 after surgery. Why is G.P. being treated with this immunosuppressive regimen?

The major goal of immunosuppressive therapy is to prevent rejection and infection with minimal adverse effects and to ensure long-term patient and graft survival as well as improved quality of life. Overall acute rejection rates are <15% during the first year after kidney transplantation. Most of these episodes respond to acute antirejection therapy.

No consensus exists on the best induction and maintenance immunosuppressive regimen, and selection primarily depends on the program and the specific organ to be transplanted. Although studies have evaluated the various regimens, comparisons are influenced by differences in donor selection and condition, organ preservation and procurement, organ ischemic (cold and warm) time, recipient's pretransplant conditions, comorbid and high-risk or low-risk immunologic factors, surgical procedures, postoperative management and monitoring, and length of follow-up. Another important consideration is that many of the these agents show significant effects during the first year, but fail to show a significant impact on long-term effects such as chronic rejection and graft survival[3] The choice of a particular regimen generally depends on the risk factors present at the time of transplantation. During this early time period, because the risk of acute rejection is highest in the first few weeks to months, the number of agents, doses, and target drug concentrations are higher than later on after transplantation.

Most initial combination immunosuppressive drug regimens rely on two to three maintenance agents, although in some cases monotherapy has been used, depending on organ type and risk factors. Common combination regimens include a CNI (tacrolimus and cyclosporine) with MPA or sirolimus/everolimus, and prednisone. The most common regimen is tacrolimus, mycophenolate, and prednisone along with short-term administration of a monoclonal antibody (alemtuzumab, basiliximab) or a polyclonal antibody (rabbit antithymocyte globulin). Regimens that avoid steroids and CNIs, or use a short course, in the early transplantation period, or are withdrawn some time (usually several months) after transplantation in an attempt to avoid the long-term side effects of these agents, are another option. In HLA-identical, living-related kidney transplants, dual therapy (e.g., tacrolimus or mycophenolate and prednisone) gives excellent results; however, acute rejection may still occur, as well as with other regimens. Combination therapy is used to take advantage of different mechanisms of action and to reduce drug toxicity by using sequential therapy and smaller doses of multiple agents rather than larger doses of any agent used alone. These multidrug combinations can lead, however, to increased drug costs, compliance issues, a higher incidence of infection and malignancy, and difficulty in assessing and managing adverse effects.[9]

Because G.P. is receiving a deceased donor transplant and is considered an immunologically high-risk recipient (he is African-American),

---

an antibody plus several maintenance agents would be appropriate. He is started on tacrolimus, mycophenolate, and prednisone. This combination based on the literature is the most effective.[15]

After the first 6 months, drug dosages are reduced over time and maintained at a stable dose for 6 months to 1 year. In G.P., tacrolimus cyclosporine, sirolimus, and everolimus doses are adjusted based on target trough concentration ranges, which are reduced over time as well. MMF may be discontinued later. Although the discontinuation of a drug may reduce adverse effects, it must be counterbalanced against the risk of rejection and potential graft loss. Monotherapy, generally with tacrolimus or cyclosporine, may be achieved in low-risk kidney, liver, transplant recipients at some time after transplantation. Most patients require lifetime immunosuppression.

CASE 34-1, QUESTION 2: What is induction therapy and which is the preferred agent for G.P?

Induction therapy after transplantation refers to the use of an antibody, typically at time of transplant and during the first few days after transplant. rATG, alemtuzumab, and basiliximab are induction agents. Acute rejection and delayed graft function (need for dialysis during first 7 days after transplant) can occur in the early transplant period. Both of these have a negative impact on graft survival. Antibody induction reduces the incidence of early acute rejection, delayed graft function, and has typically been used in immunologically high-risk patients. They allow the use of lower doses, or slower introduction or sequential use of maintenance immunosuppression. They are a major component of early therapy in high-risk patients. Their use in patients at low-to-moderate risk has increased, often as a means of reducing or avoiding the use of CNI and steroids. Currently, approximately 80% of all kidney transplants receive induction therapy, with rabbit antithymocyte globulin making up about 60%.[2,26]

rATG was chosen as induction because G.P. is African-American and is at higher risk for acute rejection. In general, rATG appears to be more effective than ATGAM (horse ATG) and is the antibody of choice. rATG, when used for induction, results in reduced acute rejection, improved survival, and manageable side effect profile. In kidney transplants, this agent is effective in reducing acute rejection and improving short- and long-term graft survival compared to horse ATG and especially in high-risk patients.[26]

Thymoglobulin and Antithymocyte Globulin

DOSING AND ADMINISTRATION

CASE 34-1, QUESTION 3: How would rATG be administered and monitored in G.P.?

Both rATG and horse ATG are effective as induction therapy, although not FDA approved, and as treatment of acute rejection. The dose of rATG ranges from 1 to 6 mg/kg but is typically 1.5 mg/kg/day, and the dose of horse ATG is 10 to 20 mg/kg/day, but is typically 15 mg/kg/day. These drugs can be diluted in 0.9% NaCl for injection and administered for 4 to 6 hours. Both are usually infused into a high-flow central vein to reduce pain, erythema, and phlebitis at the injection site. Peripheral administration has been used successfully with rATG[27] Skin testing is recommended before horse ATG use, but not rabbit-derived rATG. Patients previously sensitized to horse serum are at risk for an anaphylactoid reaction, but the prevalence of anaphylaxis has diminished with improved purification of this product. Patients with a positive pretherapy skin test could undergo desensitization, but alternatives, such as rATG, may be substituted.[18]

DOSE REGIMEN AND DURATION OF THERAPY

The first dose of rATG is usually given intraoperatively. Intraoperative administration of rATG reduces the incidence and severity of delayed graft function as compared with postoperative administration. Duration of therapy with rATG or horse ATG is 3 to 10 days for induction therapy. Protocols used to treat rejection commonly use a 7- to 10-day course of therapy. In patients such as G.P., a four-dose prophylactic regimen has been shown to be as effective as a longer regimen.[18]

ADVERSE EFFECTS

A number of adverse effects have been related to the use of rabbit antithymocyte globulin or ATG. Local phlebitis and pain usually can occur. Anaphylaxis is rare. Chills and fever, erythema, rash, hives, pruritus, headache, leukopenia, and thrombocytopenia are commonly encountered. Fever, chills, hypotension, nausea, and vomiting may be caused by the release of cytokines, such as TNF and IL-6, from lysed lymphocytes. These symptoms can be minimized by premedication with acetaminophen and diphenhydramine before each dose.

Methylprednisolone, up to 500 mg, is given 1 hour before rabbit antithymocyte globulin typically for the first two doses to minimize infusion reactions. Opportunistic viral (cytomegalovirus (CMV) and Epstein–Barr virus [EBV]) and fungal infections are the predominant delayed side effect. Susceptibility to malignancy, such as post-transplantation lymphoproliferative disease (PTLD), is also a concern. Because of the increased risk of CMV infection, patients are often given oral valganciclovir or IV ganciclovir during therapy and then oral valganciclovir, which is continued up to several months after induction.[18]

MONITORING

Vital signs should be monitored hourly during infusion, and WBC and platelet counts should be monitored daily. If the patient's WBC count drops to less than 3,000 cells/μL or if the platelet count drops to less than 100,000 cells/μL, the dose of drug is decreased by 50% or held entirely until the counts return to desired levels. Patients who receive rATG for the treatment of acute rejection may have doses held or decreased based on the degree of leucopenia and thrombocytopenia; however, the need for and response to therapy would be carefully considered in this decision.

Dosages also can be adjusted based on absolute lymphocyte counts or lymphocyte subsets as a way of maximizing efficacy and minimizing infectious complications. For example, the dose can be adjusted by using a target absolute T-lymphocyte count (CD2 or CD3) of less than 25 to 50 cells/μL, particularly if used for treatment of acute rejection. It is less common to adjust doses based on CD2 of CD3 counts when used for induction as in G.P.'s case. Using CD2 and CD3 counts results in a lower dose, less frequent dosing (e.g., every other day instead of daily), lower costs, and a lower rate of viral infection. rATG produces a more profound and longer duration of effect on lymphocytes than horse ATG; however, it does not result in a greater risk for infection and malignancy, although still a concern.[18]

CASE 34-1, QUESTION 4: Could basiliximab or alemtuzumab be used as an alternative to rabbit antithymocyte globulin?

Basiliximab is approved for use as induction therapy in kidney transplantation; however, it is also used in other organ transplant recipients. It is administered in combination with cyclosporine or tacrolimus and steroids with or without MMF or sirolimus. It has a similar safety profile compared to placebo and better safety profile than rATG. It has a limited role in high-risk populations such as G.P., or patients with high PRA or long ischemic times,

---

delayed graft function, or patients who have received a previous transplant. In these patients, induction with polyclonal antibodies is used in most centers. The large initial trials with this IL-2R antibody included very few high-risk patients or excluded them altogether. More potent agents, such as rATG, are still preferred in high-risk patients. A prospective study comparing rATG with basiliximab in high-risk kidney transplants demonstrated that acute rejection rates were lower in patients receiving rATG.[20] Basiliximab is often used for low-risk to intermediate-risk patients and in patients where CNI minimization or steroid avoidance is implemented

Alemtuzumab is another alternative and is used by some centers for low- and intermediate- to high-risk patients. It has been shown to be no less effective than rATG in high-risk patients and more effective in reducing acute rejection than basiliximab in low-risk patients.[28] Adverse effects include frequent and prolonged neutropenia, lymphopenia, thrombocytopenia, anemia, nausea, vomiting, and diarrhea. Infusion reactions can occur although it is given, as a single dose, under anesthesia, in the operating room during the transplant. As with rATG, there is an increased risk of opportunistic infections and malignancy. Rituximab has also been studied as potential induction therapy in nonsensitized or ABO-compatible transplants and found not to be very effective in this population, unlike that in ABO-incompatible recipients.[22]

Postoperative Course and Delayed Graft Function

CASE 34-1, QUESTION 5: G.P. is admitted to the transplant ward for initial post-transplantation management. His urine output during the next 3 hours has decreased from 300 to 40 mL/hour. He is receiving IV fluids at a rate equivalent to his urine output. He received 3 L of fluids in the operating room. His blood pressure is 140/83 mm Hg, heart rate is 87 beats/minute, and temperature is 36.9°C; he has no signs of dehydration. His BUN is 56 mg/dL and his SCr is 12.8 mg/dL. Another dose of furosemide 100 mg IV increased his urine output to 140 mL/hour, but his urine output returned to less than 40 mL/hour in a few hours. Fluids and IV furosemide were given again with similar results. Renal ultrasound indicates no urine leaks, fluid collections, or ureteral obstruction. A diethylenetriamine penta-acetic acid renal scan indicates good perfusion, but decreased accumulation and clearance. During the next 2 days, G.P.'s BP is 150/93 mm Hg, weight is 76 kg (4 kg higher than pretransplantation), urine output has fallen to less than 200 mL/day, and relevant laboratory values are as follows:

BUN, 85 mg/dL
SCr, 13.2 mg/dL
K, 5.8 mEq/L

The decision is made to institute hemodialysis. What has happened to G.P.'s renal function? What is the most likely diagnosis?

The initial renal function after kidney transplantation can reflect excellent, moderate, or delayed graft function. In recipients with excellent function, a good diuresis begins immediately and continues; the serum creatinine rapidly declines to less than 2.5 mg/dL within the first few days after transplantation. Most living-related transplants and between 30% and 50% of deceased donor transplants generally experience this pattern. Kidney transplant recipients with moderate or slow graft function usually experience a slower decline in serum creatinine, which stabilizes within the first week. Recipients with delayed graft function usually have anuria or oliguria, require dialysis in the early period, and take days to weeks to recover. Delayed graft function is most common in recipients of organs from deceased transplant donors, occurring in between 10% and 50% of cases.[29] The diagnosis of delayed graft function is based on clinical, laboratory, and diagnostic criteria that may vary among centers. Traditionally, delayed graft function has been defined as the need for dialysis within the first 7 days post-transplant. Slow graft function is another term that has been used to describe a lag in improvement and does not involve dialysis. Delayed graft function is influenced by the donor (age, condition of organ, prolonged ischemic time), intraoperative conditions (hypotension, fluid imbalance, ischemia or reperfusion injury), and recipient characteristics such as prior transplantation, postoperative hypovolemia or hypotension, and use of nephrotoxic drugs.[29]

In G.P., poor urine output in the first hours after transplantation and subsequent oliguria, the exclusion of other causes of acute tubular necrosis, the results of the renal scan, the lack of improvement in BUN and serum creatinine, and the need for dialysis are indicative of delayed graft function. Delayed graft function reduces kidney long-term graft survival, increases the risk of acute rejection, and influences a patient's early management by requiring dialysis, increasing the length of hospital stay, and increasing the costs of therapy. It also may make the assessment of acute rejection more difficult because the patient already has impaired renal function. In delayed graft function, a renal biopsy may be obtained if no improvement in serum creatinine is seen by day 7.[29]

CASE 34-1, QUESTION 6: What adjustments should be made in G.P.'s immunosuppressive regimen at this time? Are there any therapies that can prevent or treat delayed graft function?

The adverse renal effects of CNIs may contribute to the onset of delayed graft function as well as prolong its duration. Therefore, tacrolimus may be discontinued temporarily or its dose significantly reduced. Because of this effect, some protocols do not include CNIs, use them only in low doses for the first week, or delay their use until kidney function improves. These protocols often include antibodies and provide more intense immunosuppression early after transplantation when the risk of delayed graft function and acute rejection is highest. Rabbit antithymocyte globulin is commonly used in patients with delayed graft function because it may shorten the duration and the need for dialysis when compared with the CNI. Another potential option would be to use basiliximab, which has been shown to reduce acute rejection rates and extend the time to first rejection. One concern with the use of basiliximab is that a CNI may be required sooner than with rabbit antithymocyte globulin because this agent does not provide as long a duration of protection from rejection. One should also confirm that MPA doses be maintained and continue prednisone taper. In G.P., rabbit antithymocyte globulin would be administered for 5 to 10 days, depending on improvement in his SCr and urine output, along with his current regimen of prednisone and mycophenolate. A typical dose would be 1.5 mg/kg/day or every other day, depending on his $CD3^+$ level, and WBC and platelet counts. Tacrolimus will not be started until his SCr decreases.

Recent studies have focused developing therapies that prevent or reverse delayed graft function, with mixed results. There are several therapies being tested within this context, which include therapies to inhibit p53 (I5NP), complement (eculizumab), TLR2 (OPN-305), and hepatocyte growth factor (BB3). Other therapies that have been tested include alteplase, etanercept, ischemic preconditioning, erythropoietin, and dopamine, with the later showing reduced dialysis requirements but none demonstrating improved graft survival. As this is a common and important clinical dilemma, it continues to be a significant area of research and discovery.[29]

Rejection

CASE 34-1, QUESTION 7: G.P. was started on rabbit antithymocyte globulin 1.5 mg/kg as a 6-hour IV infusion on days 0, 1, 2, and 3 for induction, but because of his delayed graft function, he received an additional dose on day 5. He received this along with his prednisone taper and MMF. Tacrolimus PO 3 mg BID was initiated on day 5 after transplant. G.P.'s urine output has increased gradually to 1,600 mL/day after stopping rabbit antithymocyte globulin. His weight has decreased to 73 kg, and the following is recorded:

BP, 142/84 mm Hg
Heart rate, 82 beats/minute
Temperature, 36.7°C
BUN, 23 mg/dL
SCr, 3.2 mg/dL
K, 4.6 mEq/L

Sixty days after stopping rabbit antithymocyte globulin, he is on a regular diet and taking all oral medications. His current medications include MMF 750 mg BID, prednisone 5 mg daily, tacrolimus 5 mg BID, ranitidine 150 mg at bedtime, dioctyl sodium sulfosuccinate 100 mg BID, amlodipine 10 mg daily, metoprolol 50 mg PO BID, glargine insulin 40 IU daily Novolog 10 IU with meals, valganciclovir 450 mg daily, and trimethoprim–sulfamethoxazole (TMP–SMX) double-strength, one tablet on Mondays, Wednesdays, and Fridays. His weight increased to 75.6 kg, and note the following:

BP, 160/94 mm Hg
Heart rate, 98 beats/minute
Temperature, 37.6°C
BUN, 30 mg/dL
SCr, 3.4 mg/dL
K, 4.8 mEq/L
Trough whole blood tacrolimus concentration, 5 ng/mL (target range 8–10 ng/mL)
Urine output decreased during the last 24 hours to 750 mL

He feels tired and has a decreased appetite, but his fluid intake has been adequate during the past day. What evidence is consistent with rejection in G.P.?

Although significant improvements in reduction in acute rejection and improved graft survival have occurred over the past decade, certain types of acute rejection and chronic rejection continue to be a major reason for graft loss in kidney transplants. Rejection episodes can be categorized as cellular and/or antibody mediated, hyperacute, accelerated, acute, or chronic. Kidney biopsy is considered the gold standard for making the diagnosis of rejection after kidney transplant. Approved criteria are used to classify and grade the type and severity of rejection.

HYPERACUTE REJECTION

Hyperacute rejection, which occurs within minutes to hours after transplantation of the allograft, is the result of preformed cytotoxic antibodies against donor-specific class I antigens. This type of rejection is rare because of ABO matching and improved HLA typing before transplant, but it remains associated with a poor prognosis. Clinically, the patient presents with anuria, hyperkalemia, hypertension, metabolic acidosis, pulmonary edema, and, in some cases, disseminated intravascular coagulopathy. A perfusion scan of the kidney would indicate no uptake.

If other causes of anuria are excluded and this diagnosis is made, then the transplanted kidney must be removed.

ACCELERATED REJECTION

Accelerated rejection usually occurs within a few days after organ transplantation. This is a result of prior sensitization to antigens that are similar to those of the donor and newly developed donor-specific antibodies to the donor graft. Accelerated rejections of transplanted kidneys occur primarily in recipients who have had prior transplantation, multiple pregnancies, or blood transfusions. These patients usually maintain good renal function for a few days before developing acute renal failure. Accelerated organ rejections generally are more resistant to pharmacologic therapy.

ACUTE REJECTION

Acute rejection is the most common type of kidney rejection in transplant recipients and most episodes respond to therapy. Most episodes of acute rejection are T-cell-mediated (cellular), although some can be B-cell (antibody or humoral)-mediated, and others are a combination of both types. Acute rejection of a transplanted kidney is associated with reduced the half-life and survival of both living-donor and deceased-donor transplants. Acute rejection often occurs in the first week to months after kidney transplantation. The prophylactic use of antibody induction may, however, delay the onset for several weeks, as illustrated by G.P.'s case. If acute rejection occurs, its onset is generally within the first year, with most episodes occurring within the first 60 days after transplantation. Acute rejection can, however, also occur at any time after transplant and can be a result of patient nonadherence (also called noncompliance) to medications and monitoring. The clinical presentation of patients with acute rejection of a kidney ranges from an asymptomatic patient with mild renal dysfunction as indicated by an elevated serum creatinine, which is common, to patients presenting with a flulike illness, hypertension, and acute oliguric renal failure. G.P. presents with subjective complaints of malaise or tiredness and lack of appetite. Such nonspecific complaints occur often in patients with rejection and can be accompanied by myalgias. Objectively, G.P.'s increased weight, hypertension, decreased urine output, and increase in serum creatinine are consistent with acute kidney rejection. In addition, the tacrolimus trough concentration is low, suggesting inadequate immunosuppression. Acute rejection of a transplanted kidney must be distinguished from CNI nephrotoxicity, and infections (e.g., pyelonephritis, CMV, polyomavirus BK) also must be ruled out. Although the clinical evidence in G.P. probably represents an acute cellular rejection, a kidney biopsy is the gold standard for establishing the diagnosis. Biopsy results usually are available within 6 to 8 hours. If there is acute rejection, the biopsy will show an interstitial infiltration of mononuclear cells with tubulitis or intimal arteritis in more severe cases. The severity of acute rejection will be classified and graded according to standardized pathologic criteria and is important in determining treatment. Less severe grades will receive high-dose steroids, whereas more severe grades will often receive raATG.[6]

ANTIBODY-MEDIATED REJECTION

Antibody-mediated (previously called humoral) rejection can be either acute or chronic rejection mediated by antibodies. Over the past several years, there has been an increased recognition of the importance and detrimental impact of this type of rejection on graft outcomes. Antibody-mediated rejection (AMR) is ≤10% of acute rejection episodes but graft loss is near 30%. Histologically, criteria for AMR differ from ACR. Presence of positive staining for the complement component C4d indicates antibody-mediated rejection, although this type of rejection can also occur with negative C4d. Many patients either prior to transplant or after have donor-specific antibodies (DSAs) that can occur hours to years after transplantation. Antibody-mediated rejection often is associated with hemodynamic compromise and is more resistant to drug therapy.[30]

CHRONIC REJECTION

Chronic rejection is a major cause of long-term kidney graft loss after the first year. It can be either cellular- or antibody-mediated.

It occurs slowly in most cases over several years. The characteristic signs of chronic rejection are hypertension, proteinuria, and a progressive decline in renal function leading to renal failure. Because no specific treatment exists, therapy is supportive (e.g., dialysis in the case of kidney transplantation). Ultimately, retransplantation is needed. Some data suggest that some patients may benefit from some of the newer agents, such as mycophenolate and sirolimus, that are considered non-nephrotoxic, but this requires further study. The diagnosis of chronic rejection is determined by clinical signs and biopsy findings indicative of fibrosis of hollow structures and vessels within the graft. The chronic rejection of a kidney must be distinguished from chronic CNI nephrotoxicity, chronic infection, recurrence of the original kidney disease, and other causes of chronic allograft injury and other causes.

CHRONIC ALLOGRAFT INJURY

Chronic allograft injury (CAI) is a term that has been used, generally, as a diagnosis of exclusion that indicates a slow deterioration of renal function over months to years after kidney transplant, where the exact cause is unknown and results in graft loss. Immunologic and nonimmunologic mechanisms play a role in CAI. Immunologic factors that increase the likelihood of CAI include a history of acute rejection, inadequate immunosuppression, nonadherence with immunosuppressive therapy, and previous infection, such as CMV. Nonimmunologic factors are donor-related (age, hypertension, diabetes), increased ischemic times, recipient hypertension, hyperlipidemia, CNI nephrotoxicity, and elevated body mass index. Another term, interstitial fibrosis/tubular atrophy (IF/TA) is another term used to describe this deterioration. It is often considered irreversible and unaffected by increased immunosuppressive therapy.[31]

Acute Rejection Treatment

CASE 34-1, QUESTION 8: A biopsy of G.P.'s transplanted kidney shows grade 1A, moderate acute cellular rejection. G.P. is started on methylprednisolone 500 mg daily IV for three doses. His maintenance oral prednisone is discontinued and will increase MPA and TAC dose. He will be placed on a high-dose oral prednisone tapering regimen after his IV doses. Why is methylprednisolone therapy of G.P.'s first acute episode of rejection appropriate?

High-dose or "pulse" IV methylprednisolone, IV rabbit antithymocyte globulin, IV antithymocyte globulin, and oral prednisone are options to treat acute rejection in all types of solid organ transplants. A high-dose corticosteroid (usually IV methylprednisolone) is considered first-line therapy because it works very quickly in decreasing lymphocyte responsiveness, is easy to administer, and reverses at least 75% of acute rejection episodes. Rabbit antithymocyte globulin is usually reserved for steroid-resistant rejection or more severe grades of rejection. IVIG has also been used as an alternative for resistant rejection. The ideal corticosteroid dosage, route, and regimen are unknown. Corticosteroid protocols vary among transplant programs. IV methylprednisolone and oral prednisone are equally effective in reversing rejection, but oral corticosteroids are given for a longer period and have been associated with a higher incidence of adverse effects. Even though 50 mg of IV methylprednisolone has a similar lymphocyte suppressive effect as a 1-g IV dose, most programs use methylprednisolone 250 to 1,000 mg (most commonly 500 mg) IV every day for three doses and adjust the prerejection oral prednisone regimen accordingly. An example of an oral prednisone regimen is 100 to 200 mg/day tapered for 1 to 3 weeks to baseline maintenance dose. For G.P., IV methylprednisolone is appropriate because corticosteroids are considered first-line therapy for acute rejection of a transplanted kidney, and first rejection episodes (such as G.P.'s) are very responsive. In addition, G.P. has received a prophylactic course of rabbit antithymocyte globulin recently and additional doses should be avoided, if possible. Rabbit antithymocyte globulin is associated with a higher risk of CMV infection and malignancy; it is more difficult to administer, requires more intensive monitoring, is more expensive, and usually is held in reserve for corticosteroid-resistant or more severe forms of rejection.

Nevertheless, high-dose corticosteroids are not without risk. They increase the risk of infection, and long-term therapy can induce ocular, bone, cardiovascular, and endocrine abnormalities. Although G.P. will be receiving high-dose IV methylprednisolone for only 3 days, because he is diabetic, he should be monitored for hyperglycemia, and a change in his insulin requirements should be anticipated because corticosteroids can alter glucose metabolism. Short-course methylprednisolone also can mask signs of infection (e.g., fever, changes in WBC counts, pain associated with inflammation) and delay the diagnosis. Insomnia, nervousness, euphoria, mood shifts, acute psychosis, and mania also can occur with short-term corticosteroid use. If the methylprednisolone regimen is effective in reversing G.P.'s acute rejection, his serum creatinine concentration should decline within 2 to 5 days and his urine output increase.

In addition, it would be appropriate to increase G.P.'s tacrolimus dosage to 7 mg twice a day because the concentration is low (5 ng/mL) and low trough has been associated with a higher risk of acute rejection. Because small changes in tacrolimus dose can increase levels disproportionately, a trough whole blood concentration should be re-evaluated in 2 to 3 days. The mycophenolate dose could be increased to 1 g BID and up to 1.5 g BID, because this dose in combination with a CNI has reduced acute rejection in African-American patients, particularly if the patient was on cyclosporine therapy. There are limited data supporting the increase of the mycophenolate dose beyond 1 g BID with tacrolimus-based regimens.[32,33] If G.P. had been on cyclosporine, another option would be to change cyclosporine to tacrolimus, which has been shown to reduce future episodes of acute rejection. Another important aspect for prevention of future rejection would be to assess G.P.'s adherence with, and understanding of, his medication regimen. Nonadherence is a major cause of acute rejection and graft loss.[34]

CASE 34-1, QUESTION 9: Six months later G.P. is noted to have another elevation in Scr. In addition, donor-specific antibodies are also detected in blood. Did kidney biopsy indicate it as AMR? How would this type of acute rejection be treated?

AMR is more difficult to treat and approaches vary. It may not respond to steroids and thymoglobulin, which is used initially. The most common treatment is plasmapheresis or immunoadsorption. These modalities are used to remove circulating antibodies, and low- or high-dose intravenous immunoglobulin for residual antibody inhibition, given after these procedures. Because of increased recognition and diagnosis, and resistance to treatment, a number of approaches are being used and investigated. Along with plasmapheresis and IVIG, rituximab may be used to treat acute AMR. Other agents, not currently approved for transplantation, are being utilized and studied as treatment, including bortezomib, which causes plasma cell apoptosis/depletion and eculizumab which is an anti C5 antibody. Given the sparsity of large-scale, randomized trials assessing which agents to utilize to treat AMR, there is no consensus regarding which should be considered first-line therapy to treat AMR, although most clinicians do utilize plasmapheresis with IVIG as a starting point, and add on the aforementioned therapies at various stages or severities of AMR.[35]

Calcineurin Inhibitor-Induced Nephrotoxicity

CASE 34-2

QUESTION 1: C.C. is a 60-year-old man who received a deceased-donor kidney transplant 3 years ago. His serum creatinine at 1 year after transplant was 1.5 mg/dL; at 2 years, it was 1.7 mg/dL; now it is 1.9 mg/dL. He says he feels fine. His BP is controlled and urinalysis is negative for protein. A kidney biopsy conducted at this time indicates that he has no signs of acute or chronic rejection, but has evidence of CNI nephrotoxicity. His current regimen is cyclosporine 275 mg BID, MMF 500 mg BID, and prednisone 5 mg daily. His current labs show the following:

Cyclosporine blood trough, 220 ng/mL (target 100–150 ng/mL)
K, 5.5 mEq/mL
Mg, 2.3 mg/dL
Uric acid 8.0 mg/dL
Why does C.C. have CNI nephrotoxicity?

CNI nephrotoxicity is one of the most common adverse effects and occurs to some degree in all patients. The rise in the serum creatinine concentration is more gradual than, and not as high as, that seen with rejection. CNI concentrations may be elevated, although some patients may experience CNI nephrotoxicity even with levels below or within the targeted therapeutic range. Two forms of CNI nephrotoxicity have been identified: functional or acute renal dysfunction and chronic nephrotoxicity.[36]

Acute CNI nephrotoxicity is more likely to occur in the first months after transplantation and associated with high CNI doses and levels. Functional renal dysfunction or acute nephrotoxicity, the most common form of renal dysfunction, is characterized by rapid reversal when the CNI dose is held or reduced. This syndrome typically is not associated with histopathologic abnormalities. Repeated episodes of transient acute renal dysfunction can result in protracted acute renal dysfunction. Recovery of renal function after repeated episodes may not be complete even if the CNI is withdrawn. Protracted acute renal dysfunction can lead to direct tubular toxicity and can be associated with the development of thrombosis of glomerular arterioles or diffuse interstitial fibrosis.

Chronic nephrotoxicity is associated with proteinuria and tubular dysfunction. Renal biopsies in allograft patients with chronic CNI-related nephropathy show tubulointerstitial abnormalities, sometimes with focal glomerular sclerosis. These findings are considered nonspecific. Recently, the role of CNI chronic nephrotoxicity in the development of irreversible chronic renal dysfunction has been challenged and thought to be overdiagnosed in many patients. However, long-term use can result in chronic nephrotoxicity, is usually seen after 6 months of therapy, and may be irreversible. In this situation, renal function progressively declines to a point that dialysis or retransplant is required. The pathophysiology of cyclosporine or tacrolimus-induced transient acute renal failure is not understood completely, but seems to be related to its effects on renal vessels. For example, CNI can induce glomerular hypoperfusion secondary to vasoconstriction of the afferent glomerular arterioles, thereby reducing glomerular filtration. One possible explanation for these effects is that cyclosporine alters the balance of prostacyclin and thromboxane A_2 in renal cortical tissue. Increased thromboxane A_2 results in renal vasoconstriction. Endothelin release from renal vascular cells stimulated by CNI also may contribute to this acute effect through its potent vasoconstrictive properties. Activation of the renin–angiotensin–aldosterone system may also play a significant role. CNI also can cause a reversible decrease in tubular function. The alterations in tubular function reduce magnesium reabsorption and decrease potassium and uric acid secretion. This may be a result of direct tubular toxicity and possibly the result of thromboxane A_2 stimulation of platelet activation and aggregation.

C.C.'s rise in serum creatinine in conjunction with an elevated cyclosporine level suggests acute cyclosporine toxicity as the most likely cause of his findings. In this case, the total cyclosporine dose should be lowered by approximately 25% to 225 mg twice a day, to keep level in target range, and C.C. should be monitored closely for resolution of any symptoms and decrease in serum creatinine or worsening if rejection results from lowering the dose. His elevated potassium and uric acid and low magnesium should correct themselves with this dose reduction if it is acute CNI toxicity. If the nephrotoxicity is caused by cyclosporine, a decrease in the serum creatinine may be evident when the cyclosporine dose is reduced. If no such reduction occurs or if the serum creatinine continues to increase, then other nonimmunologic or immunologic causes should be considered and also need to substitute calcineurin inhibitor with an agent such as sirolimus, everolimus, or belatacept.

Calcineurin Inhibitor Avoidance, Withdrawal/Conversion, or Minimization

CASE 34-2, QUESTION 2: Would it be appropriate to withdraw cyclosporine in C.C.? If attempted, how could this be accomplished?

Cyclosporine and tacrolimus are associated with a number of metabolic, cardiovascular, neurologic, and cosmetic side effects but the most concerning is nephrotoxicity, which is a contributor to graft loss. The potential benefit of withdrawing cyclosporine would be to reduce toxicity, but this has to be weighed against the risk for rejection, graft loss, and toxicities of replacement agents.

Concern for chronic nephrotoxicity, as well as other long-term side effects, has led to the development of cyclosporine or tacrolimus minimization, withdrawal or substitution/conversion protocols, using agents, such as mycophenolate or sirolimus, everolimus, belatacept, or protocols using low doses of cyclosporine or tacrolimus.

Antibody induction, sirolimus, everolimus, mycophenolate, and belatacept, which are not associated with nephrotoxicity, have been evaluated in combination protocols that attempt to avoid, minimize, or withdraw CNI. Protocols completely avoiding

CNIs usually contain combinations of these agents. Studies, which were usually done in low-risk populations, observed lower serum creatinine levels and fewer CNI-induced toxicities, but were associated with higher rates of acute rejection, especially when CNI is not used at all. Other trials that compared combinations of rabbit antithymocyte globulin, alemtuzumab, or basiliximab, sirolimus, everolimus, mycophenolate, and steroids with either cyclosporine or tacrolimus withdrawal, or minimization protocols have shown equal effectiveness compared to standard therapy.[37,38]

In the case of early cyclosporine withdrawal, there is a 10% to 20% increased risk of acute rejection, but no change in graft survival. Protocols are used that withdraw the CNI or at least reduce the dose to a minimal level. Many attempts are within the first 3 to 12 months after transplantation in the hope that the nephrotoxic effects can be reversed before significant chronic damage occurs. These approaches add mycophenolate, sirolimus, or both as the CNI is withdrawn or reduced in dose, but they have been primarily tested in low-risk patients. Data with sirolimus suggest that patients without proteinuria and an estimated glomerular filtration rate greater than 40 mL/minute in the first year had better renal function. Whether this applies to other agents remains to be determined. Usually, when sirolimus is added to the CNI regimen, the CNI dose is reduced by 50% initially and in some cases slowly withdrawn altogether during several weeks to months. Improvement in serum creatinine may be seen initially, which may be attributed to the diminution of the CNI vasoconstrictive effects.

CNI minimization or withdrawal may not reverse the nephrotoxicity observed in C.C.’s biopsy, but it may slow the rate of deterioration of his renal function. Because C.C. is currently receiving mycophenolate, one approach would be to continue to reduce his cyclosporine, increase his mycophenolate, and maintain steroids. Another approach would be to replace the mycophenolate with sirolimus/everolimus, because he has no proteinuria and his eGFR is >40 ml/min, maintain steroids, and reduce or withdraw slowly the cyclosporine. Belatacept could also be used as replacement for cyclosporine, while continuing mycophenolate and steroids. Some studies indicate better eGFR, lower incidence of new onset diabetes after transplant, lower blood pressure, lower cholesterol, but no difference in survival compared to CNI.[37] The best regimen for someone such as C.C. has not been established, because the long-term consequences of these changes are not known. If this approach is attempted, C.C. should be watched carefully for acute rejection, and side effects of these agents, which some patients do not tolerate, and infections should be closely monitored. In addition, BP control as well as control of hyperlipidemia and hyperglycemia could improve with reduction or withdrawal of cyclosporine, depending on agent used, and could also be important in minimizing renal injury.

STEROID AVOIDANCE OR WITHDRAWAL

CASE 34-3

QUESTION 1: D.T., a 65-year-old Caucasian woman, will receive a deceased-donor kidney transplant today. She has a negative cross-match to this donor, and her previous cPRA was less than 10%. She will be given alemtuzumab 30 mg IV × 1 and methylprednisolone 500 mg IV × 1, intraoperatively. After transplant, she will be started on tacrolimus 0.05 mg/kg BID, adjusted to trough levels of 8 to 12 ng/mL for the first 3 months, along with MMF 750 mg BID. Methylprednisolone IV will be given as 250 mg IV on postoperative day 1, 125 mg IV on postoperative days 2 and 3, and no maintenance steroids thereafter. Is D.T. a good candidate for steroid avoidance or withdrawal?

Another important issue after kidney transplantation is the role of short-term and long-term steroid use. Most transplant protocols incorporate steroid therapy, although approximately 30% of transplant centers use steroids only in the early postoperative period.[2] The concept of either avoiding or discontinuing corticosteroids is appealing because they cause significant adverse effects such as diabetes, cataracts, infection, hypertension, hyperlipidemia, osteoporosis, avascular necrosis, and psychiatric, neurologic, and cosmetic effects. Steroid withdrawal or avoidance, however, may increase the risk of acute rejection, compromise long-term graft function, and necessitate higher doses of the other immunosuppressives. Steroid avoidance is defined as either no steroid use or steroid use only for the first few days after transplant. Short-term studies, generally in low-risk patients, suggest no adverse impact on short-term graft survival exists and no need is seen for higher doses of other immunosuppressives when corticosteroids are not included in maintenance regimens. These protocols have included regimens such as using induction agents, alemtuzumab, basiliximab, or rabbit antithymocyte globulin along with tacrolimus and cyclosporine, mycophenolate, sirolimus, or everolimus.[39]

Steroid withdrawal is the complete discontinuation of prednisone, typically a few months post-transplant. In the era of cyclosporine (Sandimmune)- and azathioprine-based regimens, withdrawal was associated with a high rate of acute rejection and late graft loss. With the introduction of newer agents, steroid avoidance or withdrawal has been viewed with renewed interest. Steroid withdrawal has been successful in at least 50% of kidney transplant recipients—resulting in reductions in blood pressure and lipid levels. Some protocols withdraw corticosteroids within the first few days to weeks after the initial transplantation period, whereas others withdraw them in 3 to 6 months or later after transplantation. The rate of success depends not only on the immunosuppressives used but on the population (high risk vs. low risk) and timing of withdrawal. Most success takes place in low-risk patients receiving antibody induction, such as rATG, with tacrolimus and mycophenolate with short-term steroids (≤1 week). African-Americans, pediatric patients, patients who have retransplants, highly sensitized patients, patients with a high serum creatinine (>2.5 mg/dL), and those who have had a recent rejection episode are more difficult to withdraw from steroids. This is particularly true early (<3 months) after transplantation. Withdrawal in these cases is associated with a higher rate of rejection. Later withdrawal may be attempted, but the benefits in terms of side effect profile may not be as great. Not all studies have demonstrated significance differences in side effect profiles between steroid withdrawal and continuation. Long-term outcomes are also limited using this approach. Low-risk populations are candidates for steroid avoidance or early withdrawal. First-time transplantation, living-donor, well-matched transplantation, older age, and stable graft function without rejection are factors associated with a positive benefit to steroid withdrawal.[39]

D.T. would be considered a low-risk patient because of her low immunologic activity evidenced by first time transplant, a living donor, low PRA, older age, and ethnicity. Therefore, a steroid avoidance protocol, such as the one indicated here, would be appropriate. As with other transplant recipients, she must be closely monitored for rejection and adverse effects.

Cyclosporine

CASE 34-4

QUESTION 1: B.B. is a 27-year-old, 55-kg African-American man who received a deceased donor kidney transplant. Within 12 hours of the transplantation, his immunosuppression consisted of modified cyclosporine (Neoral) 300 mg PO BID, MMF 1.5 g PO BID, and prednisone. He was taking other medicines for hypertension and infection prophylaxis. What pharmacokinetic and monitoring parameters and adverse effects should be considered with using cyclosporine?

Cyclosporine pharmacokinetic parameters exhibit significant intrapatient and interpatient variability. A number of factors are known to influence its pharmacokinetic behavior and outcomes. These include age, ethnicity, transplant type, underlying disease, time after transplantation, GI metabolism and motility; biliary and liver function; metabolism, body weight, cholesterol, albumin, red blood cell mass; and drug interactions and formulation.[40] For example, children, African-Americans, and patients with cystic fibrosis tend to have reduced absorption, increased clearance of cyclosporine, or both. Patients who are obese or who have decreased liver function will have reduced clearance. Oral absorption of cyclosporine, which has been characterized as slow, incomplete, and highly variable, is the parameter that is most significantly affected. Absorption can depend on the type of transplant, time after transplantation, presence of food and its composition, intestinal function (e.g., diarrhea, ileus), small bowel length, and presence or absence of external bile drainage. Bioavailability ranges from less than 5% to 90%.[41] In most transplant recipients, cyclosporine absorption increases over time.

Because the original cyclosporine (Sandimmune) absorption was so poor and erratic, the IV route was used for the first few days after transplantation, particularly after liver transplantation. Cyclosporine can be given IV as a continuous infusion (2–3 mg/kg/day) or intermittently (2.5 mg/kg/day) over 2 to 6 hours divided into two equal doses. Sandimmune is used in very few patients today.

Neoral and Sandimmune are not bioequivalent and, therefore, not interchangeable. Neoral produces a higher maximum concentration (C_{max}), shorter time to C_{max} (T_{max}), and higher area under the concentration–time curve (AUC) than Sandimmune. It has significantly less intrasubject and intersubject pharmacokinetic variability, and a better correlation exists between single doses and trough concentrations and AUC than Sandimmune. The bioavailability of Neoral is approximately 20% higher than that of Sandimmune. Several other generic capsules and liquid formulations are now available for both.

Cyclosporine is extensively distributed into red blood cells; whereas in plasma it is highly bound to lipoproteins. It is extensively metabolized by both the gut and liver cytochrome P-450 3A4 enzymes and transported by P-glycoprotein. The average half-life is about 15 to 20 hours. Cyclosporine is an inhibitor of CYP3A4 and Pgp, so it can interact with other drugs.[41]

Cyclosporine can cause a number of adverse effects, of which nephrotoxicity is the most frequent and worrisome. Other major effects include hypertension, hyperlipidemia, tremors, headaches, seizures, paresthesias, hypomagnesemia, hypokalemia or hyperkalemia, hyperuricemia, hyperglycemia, gout, gingival hyperplasia, hirsutism, hemolytic–uremic syndrome, and hepatotoxicity. If these occur, they generally respond to a reduction in dose or concentration although some cases require discontinuation of cyclosporine.[42]

Cyclosporine concentrations are monitored to prevent toxicity, optimize efficacy, and assess patient compliance to the prescribed regimen. Most institutions monitor trough cyclosporine levels. During the early postoperative period, cyclosporine levels are often measured daily, keeping in mind that these may not reflect steady-state concentrations, and that dosage changes should be made every few days. The target trough therapeutic concentration of cyclosporine during the first 2 months post-transplant is 150 to 300 ng/mL with most whole blood assays. About 1 to 6 months after transplantation, the cyclosporine trough concentration target is lowered to 150 to 250 ng/mL. After 6 months, the targeted cyclosporine trough concentration is lowered even further to 50 to 150 ng/mL. These ranges differ among institutions and depend on the transplant type, time after transplantation, and other agents used. The range is reduced over time, given that less immunosuppression is required after transplantation and that the pharmacokinetics change over time. A few programs may monitor C2 levels, obtained 2 hours after a dose or determine AUC; however, these are more cumbersome. A number of assay methods are used to measure cyclosporine concentrations, and most institutions use the method that is most familiar to their transplant physicians.[43]

As in all cases, pharmacokinetic and drug level data must be interpreted in conjunction with the patient's clinical condition. In addition, deference always must be given to trends established by multiple cyclosporine levels rather than reacting to a single level. Single levels may be erroneous because of variability in dose administration, incorrect sampling time or techniques, or assay error.

B.B. was started on Neoral 10 mg/kg/day given in two divided doses. Because he is African-American, he may require even higher doses, because the of the increased gut metabolism of cyclosporine in this population. His trough concentration will be monitored closely and adjusted if necessary. Once B.B. is home, cyclosporine monitoring is necessary less frequently and eventually only every 1 to 2 months. He should be watched closely for signs of rejection and toxicity.

CASE 34-4, QUESTION 2: B.B. developed GI intolerance, nausea, vomiting, and diarrhea, to both mycophenolate products (mycophenolate mofetil and mycophenolic acid sodium) and cannot take either one anymore. A decision is made to use an mTOR inhibitor, sirolimus or everolimus instead. What would be important pharmacokinetic considerations, an appropriate regimen, and monitoring parameters for this agent?

mTOR Inhibitors

Sirolimus, and more recently everolimus, could be used as a substitute for other immunosuppressives. Experience and literature is more extensive with sirolimus.[16]. Sirolimus can be used in the immediate post-transplant period although impaired wound healing and lymphocele development in kidney transplantation have limited its use in the early period. In the case of liver transplantation, its use is contraindicated in the early post-transplantation period because of hepatic artery thrombosis. Sirolimus can be added later, as is the practice in many centers, as replacement for or minimization of cyclosporine, tacrolimus, steroids, or mycophenolate. In addition, sirolimus may be used as a substitute for these agents in patients predisposed to or with evidence of malignancy.[44] Early experience advocated an initial loading dose followed by a once-daily maintenance dose; however, because of its adverse effect profile, not all centers use loading doses. The starting maintenance dose is 2 to 5 mg. The typical loading dose is 6 mg followed by 2 mg every day. In high-risk patients, such as African-Americans, a 15-mg loading dose and 5-mg daily dose is recommended along with cyclosporine. Other centers have used loading doses of 10 to 15 mg, followed by 5 to 10 mg/day for the first week with target troughs of 10 to 15 ng/mL for the first month and 5 to 10 ng/mL thereafter when used with tacrolimus. Sirolimus is often given 4 hours after the morning dose of cyclosporine. If administered at the same time as cyclosporine, sirolimus concentrations are on average 40% higher.[45]

As with other immunosuppressives, sirolimus is associated with a number of side effects, including impaired wound healing, lymphedema, oral ulcerations, hypercholesterolemia, hypertriglyceridemia, diarrhea, arthralgias, epistaxis, rash, acne, leukopenia, thrombocytopenia, nausea and vomiting, lymphocele, hypokalemia, anemia, hypertension, pneumonitis, reproductive endocrine disorders, and infection. Dose-related hypertriglyceridemia, as well as hypercholesterolemia, occurs within the first few weeks of therapy and is sufficiently significant to require intervention with lipid-lowering agents, although it may respond to dosage reduction to some degree. Leucopenia and thrombocytopenia are also dose related. Sirolimus is associated with the development of proteinuria in kidney transplant recipients. The exact mechanism is unknown, but many transplant centers are now routinely monitoring for proteinuria in patients on sirolimus therapy and generally avoid its use in patients with preexisting proteinuria. Unfortunately, adverse effects are often the reason for discontinuing this agent in many patients.[46]

Trough blood concentration monitoring plays an important role in the dosing of sirolimus. Trough concentrations correlate well with sirolimus AUC. Because it has a longer half-life than the CNI, concentrations are obtained less frequently and only 5 to 7 days after a dose change. The target trough is usually 5 and 15 ng/mL; however, this continues to be refined with more experience. Early studies achieved concentrations greater than 15 ng/mL, especially when used without a CNI, which were associated with a greater immunosuppression and adverse events. Because

---

sirolimus is synergistic with CNIs, the target concentrations of the CNIs are also reduced when these agents are used together. Target tacrolimus trough targets are 5 to 10 ng/mL, and the cyclosporine trough targets are 75 to 100 ng/mL, and in some patients lower, when used with sirolimus.[46]

B.B. could be started on sirolimus at 2 to 5 mg daily. Sirolimus blood trough concentration should be obtained 5 to 7 days after initiation. B.B.'s cyclosporine may need to be reduced if concentrations exceed 100 ng/mL. Monitoring parameters should include a fasting lipid panel, complete blood count, chemistries, and electrolytes. If everolimus was used, the starting regimen would be 0.5 mg twice daily. Everolimus blood concentrations should be obtained in 3 to 4 days after initiation. Target trough goal would be 3 to 8 μg/mL. Monitoring parameters would be similar to sirolimus.

Post-transplantation Metabolic and Cardiovascular Complications

CASE 34-5

QUESTION 1: J.F. is a 28-year-old African-American man who received a kidney transplant 8 weeks ago secondary to focal segmental glomerulosclerosis. His medical history is significant for hypertension. Before the transplant, he was taking lisinopril 20 mg PO daily and amlodipine 10 mg PO daily. After the transplant, amlodipine 10 mg PO daily was continued. J.F. was started on tacrolimus 8 mg PO BID and MMF 1 g PO

BID. He also receives 10 mg prednisone PO twice daily and will be tapered down during the next 6 weeks to 5 mg PO daily. J.F.'s tacrolimus trough concentrations have been between 10 ng/L and 14 ng/L. During the next 12 weeks, he will be maintained on a dose of tacrolimus to achieve trough concentrations between 8 ng/L and 12 ng/L. J.F. currently weighs 95 kg and is 6 feet tall. His body mass index (BMI) is 28.5 kg/m^2. After transplant, he has required a sliding-scale regular insulin regimen to maintain an appropriate blood glucose level and was discharged on an insulin regimen that included lispro and glargine insulin. His BP readings during the past 2 weeks have ranged between 145 and 155/90 and 95. Fasting lipid panel is a total cholesterol, 261 mg/dL; LDL, 161 mg/dL; HDL, 40 mg/dL; and triglycerides, 200 mg/dL.

Why would J.F. have issues with controlling his blood glucose levels, blood pressure, lipid levels, and prevention of bone fractures after transplant?

Post-transplantation diabetes mellitus (PTDM) has also been referred to new onset diabetes after transplant (NODAT) and is another common problem that appears in transplant recipients. Diabetes significantly affects morbidity and mortality in transplant recipients. It is often a preexisting condition in renal transplant recipients and a cause of ESRD. In recipients of other organs, such as livers, diabetes is common as well, both as a preexisting condition and as a post-transplantation complication. The definition of PTDM varies among studies. It has been based on symptoms, plasma glucose and HgbA1c levels, oral glucose challenge results, or the need for insulin or oral antidiabetic drugs after transplantation. Reported rates are 3% to greater than 40%, with most cases of PTDM occurring within the first year after transplantation. Risk factors, besides pretransplantation diabetes, include advanced age, family history, CMV infection, certain HLA phenotypes, race (African-American or Hispanic), increased BMI, and hepatitis C infection in the liver transplant population. One of the most critical factors in the development of PTDM is the immunosuppressive regimen. Cyclosporine, tacrolimus, and prednisone are all associated with PTDM. The CNIs appear to have a direct toxic effect on the pancreatic beta cells leading to decreased insulin synthesis and secretion; this effect seems to be dose-related and generally reversible. Although still debated, the literature suggests that tacrolimus is more likely to cause PTDM than cyclosporine. Additionally, conversion from tacrolimus to cyclosporine has been useful in some patients. Prednisone is a major contributor to PTDM via multiple effects on beta cell sensitivity to glucose and ability to release insulin and insulin resistance in multiple tissues. Sirolimus has also been implicated in development of PTDM, although its role and mechanism is unclear. Other risk factors, such as CNI drug concentrations, steroid doses, transplant type, and time lapsed after transplantation, must also be considered.[47] As with diabetes in the general population, a similar intensive approach in controlling blood glucose should be undertaken. Also, other conditions (e.g., hypertension and hyperlipidemia) should be managed aggressively to reduce cardiovascular and kidney damage. Reducing or withdrawing diabetes-inducing immunosuppression as much as possible without jeopardizing graft function or using agents that are nondiabetogenic (such as mycophenolate) may be beneficial. One important aspect of post-transplant diabetes management is to realize the differences in pharmacologic management in this population, as compared with patients who are not transplant recipients. Often, in the immediate post-transplant period, because of the rapidly changing organ function and the dramatic tapering of corticosteroids, a patient's antidiabetic medicines may need frequent adjustment. During the first several weeks post-transplant, insulin is the agent of choice owing to the ability of the clinician to use sliding scales, the availability of several insulin products, and the ease in changing doses. Once patients are stabilized on their immunosuppressant regimen, and their organ function also, the use of oral antidiabetic agents can be introduced or restarted. Metformin, glitazones, gliptins, and sulfonylureas have been used in kidney transplants, but the use of oral agents is often dictated by renal function. Other considerations would be liver function and weight gain.[48]

J.F. was not diabetic pretransplant but is now requiring insulin. By some clinicians' definitions, he would be classified as having PTDM. Others would wait to see whether J.F. still required insulin after his immunosuppressant regimen was tapered to lower levels. In either regard, because J.F. is African-American, he is considered at high risk for the development of PTDM. At this point, J.F.'s diabetes should continue to be controlled on an insulin regimen. Once J.F.'s immunosuppression regimen is stable, he could be switched to oral antidiabetic agents if needed. J.F. should be counseled on diet and exercise to help control his blood glucose level. Other pharmacologic interventions that may help prevent long-term diabetes in J.F. is changing his tacrolimus to cyclosporine and reducing or withdrawing his prednisone. The risks and benefits of changing immunosuppressant regimens must always be weighed. For instance, changing his tacrolimus to cyclosporine, or reducing or removing J.F.'s steroids, may reduce his blood glucose level and may prevent PTDM, but it also will put J.F. at higher risk of developing acute rejection.

Post-transplant Hypertension

CASE 34-5, QUESTION 2: What pharmacologic options would be used for J.F.'s hypertension?

Cardiovascular disease is very common in patients with ESRD and after kidney transplantation. These patients with prior ESRD can have CAD, LVH and CHF, and arrhythmias and valvular heart disease. Cardiovascular disease after transplant is associated with graft loss and lower patient survival. In those recipients who die with a functioning graft, 40% die secondary to a cardiovascular event. Some immunosuppressives, including

cyclosporine, tacrolimus, and steroids, contribute to the development of hypertension. Studies have indicated that blood pressure is higher, with high nighttime systolic blood pressure, and more difficult to manage in patients on cyclosporine compared with tacrolimus.[49] The appropriate blood pressure goals are similar to those in the general population, that is, less than 140/90 mm Hg in patients without proteinuria, as seen in this case. Nonpharmacologic therapies should be implemented; however, in transplant recipients, pharmacologic management is a key, often requiring multiple antihypertensives.

Pharmacologic agents used in transplant recipients are the same as those used in the general population. In the transplant recipient, one must consider the drug interaction profile and comorbidities. For example, nondihydropyridine calcium-channel blockers (CCBs), such as amlodipine, are less likely to interact with CNIs than diltiazem or verapamil. CCBs may also ameliorate some of the vasoconstrictive effects produced by the CNIs. In many programs, CCBs are considered first-line therapy. β-Blockers such as metoprolol are also frequently used in transplant recipients. Many recipients have or are at risk for coronary artery disease, and these agents can be effective in these situations. Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) can be used in transplant recipients, those with LVH. Historically, these agents were avoided, because of concern for their association with impaired kidney function. However, these have significant cardiovascular and renal benefits in patients with comorbidities such as diabetes, proteinuria, and congestive heart failure. Their use in transplant recipients has increased and is introduced shortly after transplant to months after transplant when renal function is more stable. Certainly if an ACE inhibitor or ARB is used, SCr and potassium levels must be monitored closely. Diuretics are useful in patients with evidence of fluid overload. In refractory patients, agents such as clonidine, hydralazine, and minoxidil may be required. In J.F.'s case, because he is already on amlodipine, a second agent such as lisinopril or metoprolol would be appropriate at this time with close monitoring and follow-up.

Post-transplant Hyperlipidemia

CASE 34-5, QUESTION 3: What would be an appropriate lipid-lowering therapy for J.F.'s hyperlipidemia?

Hyperlipidemia is another cardiovascular issue that must be addressed in transplant recipients. As with hypertension, it is fairly common pretransplant and post-transplant. It is associated with negative cardiac outcomes and reduced graft and patient survival in transplant recipients. Immunosuppressives including cyclosporine, tacrolimus, steroids, sirolimus, and everolimus can cause elevations in total cholesterol, LDL, and triglycerides, and also reduce HDL. Goals of treatment are primarily based on targeting an LDL of less than 100 mg/dL. Treatment involves diet, which alone appears to have minimal effect; therefore, pharmacologic treatment is usually required. Agents utilized in the nontransplant population are effective in reducing lipids in transplant recipients. Considerations in selecting treatments for hyperlipidemia include drug interactions with the immunosuppressives and the side effect profile. Statins are considered first-line treatment and have substantial evidence to support their use. Cyclosporine can increase concentrations of simvastatin and rosuvastatin, therefore limiting their doses and increasing potential for adverse events. Atorvastatin and pravastatin are often used and appear to be safe and effective in this population. Fibrates, ezetimibe, bile acid binders, and niacin are considered second-line agents.[49] In J.F., atorvastatin would be an appropriate choice.

Post-transplant Osteoporosis

CASE 34-5, QUESTION 4: Would osteoporosis and bone fractures be a concern and what would be appropriate therapies in this patient?

Rapid bone loss with the subsequent development of osteopenia or osteoporosis is another common post-transplantation disorder. Osteoporosis increases bone fragility and eventually leads to fracture. Studies estimate that osteoporosis occurs in 11% to 56% and fractures 5% to 44%, and increases in time in the transplant population. Osteoporosis risk factors for transplant recipients are similar to those in the general population included. Additional risk factors in kidney transplant include time on hemodialysis before transplant, vitamin D deficiency, pretransplant PTH and FGF-23 levels, diabetes, and steroid dose. Patients with ESRD commonly have at least some evidence of renal osteodystrophy, which includes hyperparathyroidism, osteomalacia, osteosclerosis, and adynamic or aplastic bone disease. Many kidney transplant recipients have already been exposed to medications that can affect bone and mineral metabolism, such as corticosteroids and/or loop diuretics.

Drugs used to prevent organ rejection predispose patients to osteoporosis, especially corticosteroids. The most dramatic reduction in bone loss after transplantation occurs within the first 3 to 6 months, when high doses of steroids are tapered to prednisone doses equivalent to 7.5 to 10 mg every day. As noted, corticosteroid-free or rapid-taper corticosteroid immunosuppressant regimens are being used to minimize or prevent post-transplant bone disease. Most studies suggest a minor effect of CNI on bone. Other currently used agents appear to have little or no effect. Most recommendations are based on the American College of Rheumatology's guidelines for the prevention and treatment of corticosteroid-induced osteoporosis. These recommendations focus on providing calcium and vitamin D (variable dosing depending on kidney and liver functions) to patients who will be receiving continuous corticosteroid therapy. Patients with osteopenia or osteoporosis with bone mineral density scans using dual-energy X-ray absorptiometry (DXA) scans, calcium, and vitamin D analogs are recommended in conjunction with either a bisphosphonate or calcitonin or teriparatide.[50,51]

Clinical trials have demonstrated that bisphosphonates and vitamin D or activated vitamin D analogs are effective in reducing or stabilizing bone loss but fail to show significant improvement in bone fracture rates, bone pain, or immobility owing to bone disease.

Although J.F. is young and likely may not have severe bone disease, a DXA scan should still be performed, as well as FRAX score should be determined. Phosphate, calcium and parathyroid levels, 25OH vitamin D levels, and eGFR should be assessed prior to initiation of any therapy. He could be given calcium and vitamin D because he is receiving steroids, unless he has a contraindication to this therapy. Based on the results of J.F.'s DXA scan, he may need to receive either a bisphosphonate or an activated vitamin D analog, such as calcitriol, vitamin D, and possibly calcium supplementation. A repeat DXA scan should be performed in 1 to 2 years. J.F. should be carefully counseled on how to take his medicine correctly and monitored for adverse effects.

BK Polyomavirus Infection

CASE 34-6

QUESTION 1: K.T., a 45-year-old white man, is now 16 months post-transplant. His post-transplant course has been complicated by two rejection episodes. The first was severe and required rabbit antithymocyte globulin therapy; the second was a mild rejection several weeks later that was adequately treated with three pulse doses of 500 mg IV methylprednisolone. His current immunosuppressant regimen consists of tacrolimus 8 mg PO BID, MMF 1 g PO BID, and prednisone 10 mg PO daily. In addition, he is receiving amlodipine 10 mg PO daily, benazepril 10 mg PO daily, pravastatin 40 mg PO at bedtime, and calcium with vitamin D 500 mg/400 IU PO BID. Today, he is in the transplant clinic for a routine follow-up visit. He has no complaints and says he has been feeling "great," although he has noticed some blood in his urine during the past couple of weeks. Because of this, a urinalysis is ordered in addition to the standard laboratory values. The results are as follows:

Na, 145 mEq/L
K, 4.2 mEq/L
Cl, 104 mEq/L
HCO3, 26 mEq/L
BUN, 32 mg/dL
SCr, 2.7 mg/dL
Ca, 10.1 mEq/L
Phosphorus, 4.5 mg/dL
Glucose, 110 mg/dL
Amylase, 50 IU/L
Lipase, 32 IU/L
WBC count, 7.7 cells/μL
Hgb, 10.4 g/dL
Hct, 31%
Tacrolimus trough, 9 ng/mL
Urinalysis, color yellow
Specific gravity, 1.013
pH, 7.0

Protein, 100 mg/dL
Glucose, negative
Ketones, negative
Bilirubin, negative
Blood, moderate
Nitrite, negative
Leukocyte, negative
Squamous epithelial cells, 3 cells/high-power field
Bacteria, negative

Urinalysis revealed “decoy” cells, and plasma BK virus–PCR was greater than 10^4. Because of an increased serum creatinine, a percutaneous kidney biopsy is performed. The pathologist reviews the histology of the tissue sample and determines that it is consistent with polyoma-associated nephropathy. What is BK polyomavirus? How is it diagnosed and what are its clinical manifestations?

BK virus is a human polyomavirus, first isolated in 1971. Polyomaviruses are small, nonenveloped viruses with a closed, circular, double-stranded DNA sequence. Little is known about the transmission or about the primary infection of BK virus. It is believed that viremia during the initial exposure results in systemic seeding and subsequently becomes a latent infection. The kidney is the main site of BK virus latency in healthy people. More than 50% of the general population express BK virus antibodies by age 3 years. Immunosuppression after transplantation probably leads to the reactivation of the virus, but other factors, such as organ ischemia and coinfection with other pathogens, may contribute to reactivation. Reactivation inevitably leads to viruria or viral shedding into the urine. Asymptomatic viruria occurs in approximately 10% to 45% of kidney transplant recipients.[52]

Diagnosis of polyoma-associated nephropathy is made by careful review of clinical, laboratory, and histologic findings. Patients are often asymptomatic, although hematuria has been noted in some patients. Clinically, BK virus nephritis mimics acute rejection, and increases in serum creatinine often lead to a tissue biopsy. Tissue histology is similar to cases of acute rejection and BK virus nephritis, with mononuclear infiltration as the predominant finding. The abundance of plasma cells, prominent tubular cell apoptosis, collecting duct destruction, and absence of endarteritis are features that may distinguish BK virus nephritis from acute cellular rejection. Although BK virus has been implicated in up to 5% of all cases of interstitial nephritis (of which 30% go on to graft failure), it is still unclear whether asymptomatic biopsy findings in the kidney transplant recipient are a prognostic indicator. Decoy cells in the urine and BK virus–PCR in blood are used as screening tools. Blood or plasma BK virus–PCR is a more sensitive and stable test, and correlates better with renal dysfunction than decoy cells. The American Society of Transplantation recommends screening for BK virus in all kidney transplants, by measuring serial BK PCRs monthly for the first 3 to 6 months post-transplant, then every 3 months until the end of the first year post-transplant, whenever there is an unexplained risk in serum creatinine and after treatment of acute rejection. If the BK–PCR is consistently >10,000 copies/mL, it is recommended to reduce immunosuppression.[53]

Most cases of polyoma-associated nephropathy occur within the first 3 months after transplantation, although a number of cases have been reported as long as 2 years after transplantation. The major risk factor for the development of polyoma-associated nephropathy and subsequent graft dysfunction or loss is the degree of immunosuppression. In addition, accelerated graft loss has been demonstrated in patients who received antilymphocyte antibodies in the presence of polyoma-associated nephropathy misdiagnosed as an acute rejection episode. K.T., like many patients with BK virus, is asymptomatic with an elevated serum creatinine. Because K.T. has received higher doses of immunosuppression recently to treat two acute rejection episodes, he is at higher risk for developing BK virus nephritis.

TREATMENT

CASE 34-6, QUESTION 2: K.T. is told to stop taking MMF and to reduce his tacrolimus dose to 4 mg PO BID with target trough levels less than 6 ng/mL. Why was K.T.'s immunosuppressive regimen significantly reduced?

Because BK virus reactivation and BK nephritis are strongly associated with the degree of immunosuppression, reduction in, or removal of, immunosuppressant agents is considered first-line therapy and most effective approach. Beneficial clinical responses have been demonstrated in some patients when the dose of CNI is reduced and/or other agents removed. Not all patients, however, respond to this maneuver. In addition, reduction in immunosuppression puts patients at higher risk for an acute rejection episode. Close clinical follow-up after reduction of immunosuppression is important to ensure adequate response and to make sure the patient does not experience an acute rejection episode. In K.T.'s case, an improvement of renal function can be expected, as seen by a reduction in serum creatinine over time. Also, monitoring viral loads from both the urine and the serum has been shown to correlate with clinical disease.[54]

CASE 34-6, QUESTION 3: During the next 2 weeks, K.T.'s serum creatinine remains unchanged, and his serum and urine viral loads also remain approximately the same. Are there any additional treatment options for K.T.'s BK nephritis at this time?

ANTIVIRAL THERAPY

Cidofovir, an antiviral agent indicated for the treatment of CMV retinitis, inhibits polyomavirus replication in vitro; however, to

---

date, no well-conducted clinical trials have proved this agent to be effective in treating or preventing polyoma-associated nephropathy in the transplant population.

In a small number of case reports and case series, this agent was beneficial, but the appropriate dose and frequency are still undetermined. Most reports have used very small doses (0.25–1.0 mg/kg/dose) to minimize nephrotoxicity. It is given IV either weekly or every other week and usually continued until renal dysfunction is resolved and a decrease in the viral load occurs.

Cidofovir is associated with a high incidence of nephrotoxicity, especially at much higher doses; therefore, patients usually receive predose and postdose hydration with 0.9% NaCl boluses. Close clinical monitoring of the patient is advised if this treatment option is used. Because the doses of cidofovir currently used are approximately 5% to 10% of the standard dose used to treat CMV (5 mg/kg/dose), use of probenecid as a premedication to prevent high-dose cidofovir-induced nephrotoxicity is not advocated. Other therapies that have been tried with mixed success are IVIG and leflunomide in place of the discontinued antimetabolite, such as mycophenolate. Retransplantation has also been conducted with some success.[54]

LIVER TRANSPLANTATION

Indications

CASE 34-7

QUESTION 1: E.P., a 58-year-old, 78-kg man with an 18-year history of chronic liver disease secondary to hepatitis C infection, arrives at the emergency room with a 2-day history of confusion, fever up to 102.2°F, and worsening jaundice, with scleral icterus. Because the patient has severe abdominal distention, a paracentesis is performed, and 7 L of fluid is drained from his peritoneal cavity. A diagnosis of spontaneous bacterial peritonitis is made.

E.P.'s clinical status during the next several days gradually worsens, and he is moved to the intensive care unit for closer monitoring and better supportive care. E.P. continues to be severely jaundiced, with worsening liver function tests (LFTs). He becomes progressively more confused and eventually comatose requiring intubation. Within 3 days of admission into the intensive care unit, a suitable liver donor, matched for size and ABO blood group, is found and E.P. receives an orthotopic liver transplant with a choledocho-choledochostomy (duct-to-duct anastomosis). CMV serology for E.P. is negative, and the donor liver is CMV positive.

After the transplantation, E.P. is started on fluid maintenance with 0.45% normal saline; tacrolimus 2 mg NG/PO BID; and high-dose methylprednisolone with a rapid taper: 50 mg IV every 6 hours for four doses, 40 mg IV every 6 hours for four doses, 30 mg IV every 6 hours for four doses, 20 mg IV every 6 hours for four doses, 20 mg IV every 12 hours for two doses, then 20 mg IV daily; famotidine 20 mg IV every 12 hours; and ganciclovir 150 mg IV daily. Piperacillin–tazobactam 3.5 g IV every 6 hours for 48 hours was begun in the operating room. An order also is written to limit all pain medications and sedatives. E.P. returned from surgery with three abdominal Jackson–Pratt (JP) drains, an NG tube, Foley catheter, and Swan–Ganz central venous catheter. What was the indication for E.P. to receive a liver transplant?

E.P. was diagnosed with end-stage liver failure (cirrhosis) caused by chronic hepatitis C infection. Each center varies with respect to the most causes of cirrhosis leading to liver transplant, but nationwide, hepatitis C and alcohol-induced disease are the number one and two reasons for liver transplantation; however, in recent years, nonalcoholic steatohepatitis (NASH) has been increasing in incidence and is expected to become the most common indication within the next 10 years. Indications for liver transplantation in adults include cholestatic liver disease (e.g., primary biliary cirrhosis and primary sclerosing cholangitis), hepatocellular liver disease (e.g., chronic viral hepatitis B or C, autoimmune, drug-induced, NASH, cryptogenic cirrhosis), vascular disease (e.g., Budd–Chiari), hepatic malignancy, inherited metabolic disorders, and fulminant hepatic failure (e.g., viral hepatitis, Wilson disease, drug-induced or toxin-induced). Controversial indications include alcohol-induced disease and some types of hepatic malignancies. The concern with these indications is either recurrence of disease, as in the case of hepatic malignancies, or recidivism in the case of alcoholics.[55,56]

Contraindications to transplantation have decreased over the past few years. Current contraindications to liver transplantation include malignancy outside the liver, cholangiocarcinoma, active uncontrolled infection outside the biliary system, patients with alcoholic liver disease who continue to abuse alcohol, psychosocial instability and noncompliance, severe neurologic disease, and advanced cardiopulmonary disease. Patients with active infections are considered candidates after the infection has been eradicated.[56] HIV infection is not considered an absolute contraindication to transplantation.[57]

E.P. was within the age limitations for transplantation (in general, up to age 75 years is considered although exceptions are common); he had severe progressive disease and was at risk for death if he had not received a liver transplant. Because he did not have any of the listed contraindications, a liver could be transplanted emergently. His anticipated survival after transplantation at 1 year is greater than 85%; at 5 years, it is greater than 70%.[56]

Patient Monitoring

CASE 34-7, QUESTION 2: How should E.P. be monitored in the initial postoperative period?

Ideally, E.P. should be awake and alert within 12 to 24 hours after the operation, transferred from the intensive care unit to a regular bed in 1 to 2 days, and discharged home within 5 to 10 days. Because function of the transplanted liver is essential for the survival of the patient, extensive clinical, laboratory, and radiologic monitoring are necessary. E.P. has three JP abdominal drains that must be monitored for output production. The serum concentrations of BUN, creatinine, LFTs, potassium, sodium, magnesium, calcium, phosphate, and glucose should be monitored every 6 hours on the first postoperative day.[58] The surgical transplantation of a liver has been associated with coagulopathies and bleeding. Therefore, platelets, prothrombin time, fibrinogen, and factor V levels also should be monitored and deficiencies rapidly corrected when clinically indicated.[58]

Initial LFT results are highly variable; they can either increase for the first day or two after transplantation because of ischemic and reperfusion injury to the allograft, or they can decrease because of initial dilution by high-volume blood replacement. If the liver is functioning well, the LFTs, bilirubin, and prothrombin time all should begin to trend toward normal within a few days after the transplant.

Magnesium, phosphate, and calcium levels may fall in the early postoperative period and should be monitored closely. Ionized calcium serum concentrations are often monitored rather than total calcium because most patients have low serum albumin concentrations. Hypocalcemia can occur because these patients may receive large amounts of citrate through blood transfusions, which can lower serum calcium concentrations. Magnesium deficiency is common in patients with end-stage liver disease and may be exacerbated in the early post-transplantation period by tacrolimus or diuretics. Why patients experience hypophosphatemia is not fully known, but increased demand for phosphate for incorporation into adenosine triphosphate is a possible explanation. Hypokalemia or hyperkalemia can occur, depending on renal function and fluid status. Electrolyte serum concentrations should be followed and electrolytes replaced if needed (see Chapter 27, Fluid and Electrolyte Disorders).

Hyperglycemia, which is a good indication of a properly functioning liver due to its role in glucose homeostasis (gluconeogenesis and glycolysis), may need to be controlled with a continuous IV infusion of insulin initially, and then subcutaneous insulin dosed on the basis of periodic glucose measurements. In contrast, persistent refractory hypoglycemia indicates a poorly functioning liver. Hypertension, which is multifactorial, also is sometimes seen during this time and usually is treated with calcium-channel blockers or β-blockers. Renal dysfunction and neurologic complications also can occur.[58] Neurologic complications, including those that are drug induced, include oversedation, acute psychosis, depression, tremor, headaches, peripheral neuropathy, cortical blindness, paresthesias, paresis, and seizures.[59]

Additional complications that are common within the first 3 days to 3 months after liver transplantation include respiratory distress, intra-abdominal hemorrhage, biliary tract leaks and strictures, hepatic artery thrombosis, and primary graft nonfunction. Because infection is another early postoperative concern, E.P. should be monitored for bacterial, fungal, and viral infections.[58]

Tacrolimus

PHARMACOKINETICS

CASE 34-7, QUESTION 3: Seven days after his liver transplantation, E.P.'s JP abdominal drains, Foley catheter, and NG drain have been removed. Current medications include tacrolimus 4 mg PO every 12 hours; prednisone 20 mg PO daily; TMP–SMX single-strength, one tablet PO daily; and valganciclovir 450 mg PO daily. E.P.'s current laboratory values include the following:

BUN, 27 mg/dL
SCr, 0.9 mg/dL
Aspartate aminotransferase (AST), 170 IU/L
Alanine aminotransferase (ALT), 154 IU/L
γ-Glutamyl transferase (GGT), 320 IU/L
Total bilirubin, 3.4 mg/dL
Tacrolimus 9.4 ng/dL (whole blood by HPLC mass spectrometry)

What important pharmacokinetic factors should be considered when using tacrolimus after transplantation?

Tacrolimus is a highly lipophilic medication that is absorbed rapidly after oral administration; peak blood concentrations are achieved in about 0.5 to 1 hour. Oral bioavailability is usually poor, highly variable, and ranges from 4% to 89% (mean, 25%). Protein binding is approximately 99% and is mainly to erythrocytes and alpha1-acid glycoprotein. Whole blood concentrations are significantly higher than serum concentrations for this reason. Tacrolimus has a large volume of distribution and accumulates in high concentrations in tissues, including the lungs, spleen, heart, kidney, brain, muscles, and liver. Tacrolimus is predominantly metabolized in the liver through the cytochrome P-450 3A4/5 isoenzyme system and is primarily eliminated from the body as several inactive metabolites. Less than 1% of tacrolimus is eliminated as the parent compound in the urine, and renal dysfunction does not alter the pharmacokinetics of this agent. The elimination half-life ranges from 5.5 to 16.6 hours, with a mean of 8.7 hours. Varying degrees of liver dysfunction, including cirrhosis and severe cholestasis, may reduce the metabolism and excretion of tacrolimus. Pediatric patients have a higher clearance, shorter half-life, and larger volume of distribution compared with adults.[60] African-American patients may require higher dosages (0.2–0.4 mg/kg/day orally as opposed to 0.1–0.2 mg/kg/day orally), such as in E.P.[61]

DOSING

CASE 34-7, QUESTION 4: How would you initiate the dosing of tacrolimus for E.P.?

Although tacrolimus can be administered as a continuous IV infusion through a central or peripheral catheter after transplantation (initial dose 0.025–0.05 mg/kg/day), it is preferable to give it via an NG tube or orally because adverse effects, such as headache, nausea, vomiting, neurotoxicity, and nephrotoxicity, occur more commonly with IV administration. If tacrolimus is given IV, patients should be converted as soon as possible to oral therapy (initial doses of 0.1–0.3 mg/kg/day in adults and 0.15–0.3 mg/kg/day in children, divided into 12-hour intervals).[62]

In E.P., the initial starting dose was approximately 0.1 mg/kg/day given orally or through the NG tube every 12 hours. Oral tacrolimus should be administered on an empty stomach or taken consistently in relation to meals. Most institutions extemporaneously prepare an oral solution for NG tube administration because it is not commercially available.[61]

THERAPEUTIC DRUG MONITORING

CASE 34-7, QUESTION 5: E.P.'s tacrolimus concentrations are measured by whole blood HPLC mass spectrometry. Why is it important to monitor E.P.'s tacrolimus concentrations and how should his tacrolimus therapy be monitored?

Because of the large interpatient and intrapatient variability, the narrow therapeutic index, and the large number of potential drug interactions associated with this agent, tacrolimus concentrations should be monitored in patients receiving therapy. Concentrations are monitored to prevent toxicity, optimize efficacy, and assess patient adherence to the prescribed regimen. A relationship exists between concentration, efficacy, and toxicity.[62] The primary monitoring parameter used clinically is the trough concentration because trough concentrations correlate well with overall total body exposure (AUC). The target trough range is 5 to 12 ng/mL for the first 3 months and 4 to 10 ng/mL thereafter, but this can vary with each transplant center's protocols and type of transplant. Most centers are now using mass spectrometry to monitor all immunosuppressant concentrations. HPLC with mass spectrometry is a more reliable method of analysis that does not cross-react with metabolites; therefore, only parent drug is quantitated.[63]

As in all cases, pharmacokinetic data must be interpreted in conjunction with the patient's clinical condition. In addition, deference always must be given to trends established by multiple tacrolimus concentrations over that of a single concentration.

ADVERSE DRUG REACTIONS

CASE 34-7, QUESTION 6: What are the major adverse effects associated with tacrolimus and what clinical parameters should be monitored in E.P.?

Nephrotoxicity, which usually is the limiting adverse effect of tacrolimus, has been reported in more than 50% of patients in some studies.[64] This high incidence may be related to the higher dosages used in earlier trials. Fortunately, dose reduction usually reverses the acute nephrotoxicity. Because IV administration of tacrolimus during the first week has been associated with acute renal failure in 20% of patients, very few centers use this route or rapidly convert

---

to oral therapy. Presumably, liver recipients with poor graft function have a very low tacrolimus clearance and are at a greater risk for acute renal failure.[64] In a multicenter study involving 529 patients, the efficacy and toxicity of tacrolimus was compared with cyclosporine in liver transplant recipients. Both agents increased serum creatinine and decreased glomerular filtration rate comparably.[65] Thus, E.P.'s renal function should be monitored closely.

Major neurologic toxicities (e.g., confusion, seizures, dysarthria, persistent coma) occur in approximately 10% of patients. Minor neurologic toxicities occur in approximately 20% to 60% of patients and include tremors, headache, and sleep disturbances.[65] Hypertension (40%) is another common finding in patients treated with tacrolimus. A greater number of tacrolimus-treated patients, however, are able to discontinue or limit their use of antihypertensives as compared with cyclosporine. Other adverse effects include diarrhea, nausea, vomiting and anorexia, alopecia, hypomagnesemia, hyperkalemia, hemolytic uremic syndrome, alopecia, increased susceptibility to infection and malignancy, and hyperglycemia. Hyperglycemia is reported to occur more often with tacrolimus than cyclosporine. This is most likely to be seen in patients with higher tacrolimus levels, higher steroid doses, and in African-Americans. With reduction in tacrolimus and steroid doses, hyperglycemia may reverse or decrease in severity. Hirsutism and gingival hyperplasia, which occur with cyclosporine, are not seen with tacrolimus use.

Generic Tacrolimus

In August 2009, the FDA approved the first generic tacrolimus. Since that time, there are up to five commercially available generic products. There has been continued controversy and debate regarding the bio- and clinical equivalence of generic tacrolimus products, with studies providing evidence on both sides of this argument. However, recently completed FDA-solicited multicenter crossover studies conducted in organ transplant recipients have demonstrated bioequivalence. The use of generic tacrolimus has become fairly routine across most transplant centers, although clinicians continue to caution against frequent changing of different manufacturers.[66]

Tacrolimus ER

Two new products, which are once-daily extended-release formulations of tacrolimus, have recently been approved for use in the United States (Astragraf XL and Envarsus XR). Studies demonstrate a 1:1 conversion from the normal-release product yields lower peak concentrations, but similar 24 hour AUCs when using Astragraf XL. Randomized clinical trials demonstrate similar rates of acute rejection, graft loss, and death between tacrolimus ER and normal-release formulations; however, specifically within female liver transplant recipients, there was a significant higher rate of death in the ER formulation group, which led the FDA to add a black box warning to the label for Astragraf XL. A number of small follow-up studies have also demonstrated improved adherence to the once-daily formulation, although this is a controversial area of debate amongst clinicians. The conversion from immediate-release tacrolimus to Envarsus XR is 1:0.8; meaning 80% of the preconversion daily dose of tacrolimus of immediate release should be given when using the Envarsus XR formulation.[67,68]

Rejection

CASE 34-7, QUESTION 7: E.P. was discharged from the hospital. He went to stay with his brother and was followed up with laboratory tests obtained 3 times a week. The following laboratory values were obtained 2 weeks later:

AST, 36 IU/L
ALT, 52 IU/L
GGT, 65 IU/L
Total/direct (T/D) bilirubin, 1.0/0.3 mg/dL
and another week later:
AST, 158 IU/L
ALT, 322 IU/L
GGT, 321 IU/L
T/D bilirubin, 3.6/3.2 mg/dL

E.P. was readmitted to the transplant center because his LFT rise suggested acute liver dysfunction, and a percutaneous needle liver biopsy was obtained to determine the cause. On admission, he complained of lethargy, severe headaches, a mild tremor, and some pain over the area of the transplanted liver. E.P. also stated that he had not felt like eating for the last 2 to 3 days. The pathologist interpreted the liver biopsy as moderate rejection, and E.P. was given a 500-mg IV bolus of methylprednisolone followed by rapidly tapered doses of IV methylprednisolone: 50 mg every 6 hours for four doses; 40 mg every 6 hours for four doses; 30 mg every 6 hours for four doses; 20 mg every 6 hours for four doses; 20 mg every 12 hours for two doses; then back to the pretaper oral prednisone dose. Three days into the recycle, E.P.'s liver enzyme values had not improved and rabbit antithymocyte globulin therapy was initiated. Laboratory values after 10 days of thymoglobulin IV 1.5 mg/kg/day were as follows:

AST, 35 IU/L
ALT, 108 units/L
GGT, 169 units/L
T/D bilirubin, 1.0/0.6 mg/dL

The 12-hour tacrolimus trough level at the end of the treatment course was 15.2 ng/mL. E.P. was discharged and sent home with the following medications: tacrolimus 5 mg PO BID; prednisone 20 mg PO daily; clonidine 0.3 mg PO BID; felodipine 10 mg PO daily; furosemide 20 mg PO daily; co-trimoxazole one tablet daily Mondays, Wednesdays, and Fridays; and valganciclovir 450 mg PO daily. What subjective and objective evidence of liver rejection is present in E.P.?

Hyperacute rejection rarely occurs with liver transplantation; when this occurs, treatment is supportive and retransplantation is required.[69] Unlike other organs, however, the liver may function adequately, but survival is lower when the organ is transplanted across blood types (ABO incompatible) or in patients that are presensitized to the HLA antigens.[70]

ACUTE LIVER REJECTION

Although acute liver rejection can occur at any time after the transplantation, it is most commonly experienced within the first 3 to 6 months after transplant and in approximately 20% to 50% of patients treated with either cyclosporine or tacrolimus and prednisone.[68] Data in patients treated with tacrolimus, mycophenolate, and prednisone indicate lower rejection rates.[71] Late acute rejections often are a result of either nonadherence, a reduction in dose, or a discontinuation of immunosuppressive agents. These rejection episodes, although somewhat common, rarely lead to graft loss.

E.P. presented with some of the subjective complaints of rejection. Commonly, patients feel poorly and complain of anorexia, abdominal discomfort, and headache. Other symptoms, such as a low-grade fever, back pain, or respiratory distress, may rarely occur. With the use of more potent immunosuppression, symptoms are no longer commonly present with acute rejection and cannot be relied upon for early indication of rejection. Objective evidence

---

for rejection in E.P. included an abrupt rise in transaminases and bilirubin and a liver biopsy that was interpreted as "moderate rejection." These observations led to a diagnosis of rejection. Acute rejection is associated with mononuclear cell infiltration of the graft, edema, and parenchymal necrosis. Rejection should be diagnosed by biopsy using histologic criteria. Areas commonly damaged by rejection are the bile ducts, veins, and arteries, known as portal triaditis.[72]

CHRONIC LIVER REJECTION

Chronic liver rejection, also called ductopenic rejection, usually develops months to years after the transplant in less than 5% of recipients. Characteristics of chronic liver rejection include occlusive arterial lesions, destruction of small intrahepatic bile ducts (often referred to as vanishing bile duct syndrome), intense cholestasis, accumulation of foamy macrophages within the portal sinusoids, and fibrosis, which can lead to the development of cirrhosis.[72] Chronic rejection is almost always irreversible and unaffected by increased immunosuppressive therapy. Retransplantation has been considered the only viable alternative. Some patients with early ductopenic rejection unresponsive to cyclosporine-based therapy have responded to tacrolimus.[73]

Treatment of Rejection

CASE 34-7, QUESTION 8: Was the treatment of E.P.'s rejection of his transplanted liver appropriate?

E.P. was receiving maintenance immunosuppression with tacrolimus and prednisone. Double or triple therapy with tacrolimus and prednisone is commonly used as chronic immunosuppressive therapy. Although E.P.'s tacrolimus concentration appeared adequate, he was treated with a bolus dose of IV methylprednisolone because of clinical evidence that supported a diagnosis of graft rejection. This treatment decision was reasonable because high-dose corticosteroids reverse the majority of acute rejection episodes.[69] The decision to determine E.P.'s response to the initial bolus steroid dosage and the severity of rejection by biopsy also was appropriate before proceeding with further treatment. E.P. had experienced moderate rejection of his transplanted liver, and the subsequent initiation of rabbit antithymocyte globulin was reasonable because he did not adequately respond to the steroid recycle.

Rejection in adult liver transplant recipients is usually treated with 200 to 1,000 mg/day of IV methylprednisolone and tapered rapidly, similar to E.P. When patients fail to respond to recycle corticosteroid therapy, several options are available. E.P. was begun on rabbit antithymocyte globulin therapy; other options include the use of alemtuzumab. Most centers use rabbit antithymocyte globulin as a second-line agent if there is no response to high-dose corticosteroids or first line for severe rejection. The typical dose is 1.5 mg/kg/day given as an infusion for 4 to 6 hours and is continued for 7 to 14 days. Treatment of corticosteroid-resistant rejection with rabbit antithymocyte globulin is effective in about 70% to 80% of liver transplant recipients. Other adjustments in immunosuppression include the addition of mycophenolate or an mTOR inhibitor.[69]

Mycophenolate Mofetil

CASE 34-7, QUESTION 9: After the rejection episode, E.P. is started on MMF. Describe MMF's pharmacokinetic characteristics and adverse effects. How will these characteristics affect the dosing and monitoring of MMF in this patient?

In the vast majority of transplant centers, MMF has replaced azathioprine as the antiproliferative agent used in combination with antibodies, CNI, and prednisone. In E.P., MMF was not initiated immediately after transplant because he has hepatitis C, which can recur after transplant, especially with too much immunosuppression. Therefore, in his case, immunosuppression was initially minimized to limit the chances of severe hepatitis C recurrence.

PHARMACOKINETICS

Mycophenolate mofetil is a prodrug for the active form, MPA. MMF is well absorbed (bioavailability 94%) and is rapidly hydrolyzed to MPA. The C_{max} for MPA occurs between 1 and 3 hours, and it is hepatically and renally glucuronidated to inactive MPAG, which is eliminated by the kidney, but mainly excreted into the bile. Once MPAG is excreted into bile, it then may then undergo enterohepatic recycling in the GI tract, where it is deconjugated to MPA (which is reabsorbed back into the systemic circulation). Because of this recycling, a second peak occurs 6 to 12 hours after dosing. MPA has an elimination half-life of 17 hours on average; the volume of distribution is 4 L/kg, and it is highly protein-bound to albumin (98%). Protein binding correlates well with albumin, and free MPA concentrations somewhat correlate with the immunosuppressive effect. Renal impairment, liver dysfunction, and elevated MPAG concentrations in transplant recipients can reduce protein binding. This may be a function of low albumin concentrations seen in these patients.[12]

ADVERSE EFFECTS

The most commonly reported side effects for MMF are GI (anorexia, nausea, vomiting and diarrhea, gastritis), hematologic (leukopenia, thrombocytopenia, anemia), and infections. GI side effects are common, and all side effects are more common with higher dosages. Patients with GI complaints may respond to administering the dose without other medications, smaller more frequent doses, or lowering of the dose and titrating upward as tolerated.[74] If the WBC count is less than 3,000 or absolute neutrophil count is less than 1,300 cells/µL, the MMF dose should be reduced or discontinued.

DOSING

The usual MMF starting dose in adults is 1 to 1.5 g twice daily PO. Some advocate the higher dosage in high-risk patients (e.g., patients receiving another transplant, patients with a high PRA, African-Americans). The recommended regimen in patients with a glomerular filtration rate less than 25 mL/minute is 1 g twice daily PO. In children, 300 to 600 mg/m^2 or 23 mg/kg/day given 2 times a day PO has been recommended. Due to a drug interaction, doses should be higher when administered with cyclosporine (1 to 1.5 g) compared to tacrolimus (0.75 to 1 g).[12,32]

THERAPEUTIC DRUG MONITORING

Monitoring MPA plasma concentrations is controversial and not generally recommended at this time due to the lack of data demonstrating improved outcomes with TDM. There are a number of studies that have shown some benefit, with others not showing any clinical improvements with MPA TDM. In kidney transplant recipients, low MPA AUCs and troughs have been shown to correlate with acute rejection. In centers routinely performing MPA monitoring, typical $\text{AUC}_{0\text{–}12}$ targets are 30 to 60 mcg/hour/mL and troughs 1 to 3.5 mcg/mL. MPA monitoring appears to be more beneficial in protocols where CNI sparing, withdrawal, or minimization is used. Once started on MMF, E.P. should be monitored for GI and hematologic side effects, as well as for any signs and symptoms of infection and rejection.[33]

GENERIC MYCOPHENOLATE MOFETIL

In 2009, the FDA approved the use of generic MMF in solid organ transplantation. Currently, there are multiple manufacturers with approved generic formulations of MMF. These products meet FDA standards for bioequivalence and are considered AB-rated to CellCept 250-mg capsules or 500-mg tablets.[75] Currently, there are no studies demonstrating that generic MMF has produced inferior clinical outcomes or increased the risk of medication side effects, and most clinicians are comfortable utilizing the generic formulation of MMF, although frequent changes between manufacturers are not recommended.

Drug Interactions with Immunosuppressives

CASE 34-8

QUESTION 1: C.C. is a 42-year-old woman who underwent a liver transplantation 5 days ago. She was noted to be febrile, with an elevated WBC. Cultures were obtained, and her JP drainage grew Candida albicans. C.C. was started on fluconazole 400 mg daily. Her other medications included tacrolimus 3 mg BID, prednisone 20 mg daily, mycophenolate 500 mg BID (low dose due to new onset infection), valganciclovir 450 mg daily, TMP–SMX single-strength tablet daily, and esomeprazole 20 mg every night. The tacrolimus trough level is 11 ng/mL. What drugs interact with immunosuppressive agents? Will the initiation of fluconazole require any adjustments in current medication doses?

Because the immunosuppressants have complex and highly variable pharmacokinetic profiles with relatively narrow therapeutic indexes, drug–drug interactions represent a significant clinical problem. Drug interactions can be separated into two main categories: pharmacokinetic and pharmacodynamic. Pharmacokinetic interactions occur when one medication alters the absorption, distribution, metabolism, or elimination of the immunosuppressant agent.[76,77] Table 34-2 displays the most clinically relevant pharmacokinetic drug interactions that are likely to be encountered in transplant recipients and how to manage these interactions. These include drugs that alter either the absorption or metabolism of the immunosuppressants. Note that this table is not comprehensive.

Pharmacodynamic interactions occur when one medication either potentiates an adverse effect or alters the pharmacologic effects of the immunosuppressant agent.[77] An example is the use of CNI in combination with ACE inhibitors. Because both classes of agents can cause hyperkalemia and potentially decrease renal function, toxicity may be more pronounced when given in combination.[78] Pharmacodynamic drug interactions are usually more difficult to identify and require a thorough knowledge of the pharmacologic effects of the agents. Often, little or no information in the literature on these types of interactions exists to guide the clinician in determining whether this drug interaction will occur. As a general rule, if an agent is known to cause a particular toxicity that is similar to a toxicity associated with the immunosuppressant agent, then there is a high likelihood that a pharmacodynamic interaction will occur. Another example is an interaction between metoclopramide and MMF. Both agents are known to cause diarrhea, and a higher incidence or severity of diarrhea likely occurs when these agents are used together.[77]

Table 34-2

Immunosuppressant Drug Interactions

Immunosuppressant	Interacting Drugs	Mechanism	Consequence	Clinical Management
Calcineurin inhibitors (cyclosporine and tacrolimus), sirolimus and everolimus	Clarithromycin,[a] erythromycin,[a] telithromycin,[a] ketoconazole,[a] itraconazole,[a] fluconazole, voriconazole,[a] fluoxetine, fluvoxamine, citalopram, nefazodone,[a] diltiazem,[a] verapamil,[a] delavirdine,[a] ritonavir,[a] cimetidine,[a] grapefruit juice,[a] amiodarone, saquinavir, nelfinavir, indinavir, amprenavir, chloramphenicol[a]	Inhibit CYP 3A isoenzyme in the liver and intestines.	Increase the blood concentration of the IS.	Either prospectively decrease the IS dose or monitor trough concentrations and AUC more closely and adjust doses accordingly.
Calcineurin inhibitors (cyclosporine and tacrolimus), sirolimus and everolimus	Carbamazepine,[a] dexamethasone, phenobarbital,[a] phenytoin,[a] Saint-John's-wort,[a] rifampin,[a] rifabutin,[a] efavirenz,[a] nevirapine,[a] nafcillin, clindamycin	Induce CYP 3A4 isoenzyme in the liver and intestines.	Decrease the blood concentration of the IS.	Either prospectively increase the IS dose or monitor trough concentrations and AUC more closely and adjust doses accordingly.
Calcineurin inhibitors (cyclosporine and tacrolimus), sirolimus, mycophenolate mofetil, and mycophenolate sodium	Cholestyramine, colestipol, probucol, sevelamer, antacids (magnesium and aluminum containing), iron-containing products	Bind to IS and prevent absorption.	Decrease the blood concentration of the IS.	Avoid concomitant administration with IS and monitor trough concentrations.
Azathioprine	Allopurinol	Inhibit metabolism by inhibiting xanthine oxidase.	Increase the blood concentration of azathioprine.	Avoid use together or prospectively reduce azathioprine dose to one-third or one-fourth normal dose and monitor for increased toxicity.

[a] These are considered either potent inhibitors or inducers.

AUC, area under the curve; CYP, cytochrome P-450; IS, immunosuppressant.

It is important to be alert for drugs with pharmacologic effects that may alter the efficacy of an immunosuppressant.[77] For example, a drug with immunosuppressant properties, such as cyclophosphamide, could lead to overimmunosuppression of the transplant recipient and a higher incidence or severity of opportunistic infections. Conversely, a drug with immunostimulant properties, such as the herbal medication echinacea, may reduce the efficacy of the immunosuppressant agent and increase the risk of rejection in the transplant recipient.[76,77] Although agents that have pharmacodynamic drug interactions with the immunosuppressants are not absolutely contraindicated, transplant recipients should be closely monitored for either increased risk of drug toxicity or decreased drug efficacy when these agents are used in combination. When a transplant recipient adds any new medication—whether prescription, over-the-counter, or herbal—it should be thoroughly researched to determine whether there is a potential interaction with the immunosuppressant regimen.

In C.C., the addition of fluconazole will lead to a pharmacokinetic drug interaction by inhibiting the cytochrome P-450 3A4 system and may significantly increase tacrolimus concentrations. This interaction is usually evident within 2 to 5 days, and a maximal effect is seen within a week of initiating fluconazole. Therefore, C.C.'s tacrolimus dose should be reduced when fluconazole is started. Tacrolimus blood levels should be monitored, as should signs and symptoms of toxicity. Fluconazole could also influence steroid metabolism, but specific recommendations are not available. In general, drug interactions can be managed and, in some cases, may require only separate administration times. In other cases, an alternative agent can be used within a pharmacologic class that does not interact with these agents.

Infection Prophylaxis

CASE 34-9

QUESTION 1: S.C. is a 20-year-old man who underwent liver transplantation for end-stage liver disease secondary to chronic hepatitis B. Besides his immunosuppressives, he received ampicillin sulbactam 1.5 g every 8 hours for 24 hours perioperatively. After transplantation, he also was started on trimethoprim-sulfamethoxazole (TMP–SMX) double-strength (DS, 800/160 mg) one tablet Mondays, Wednesdays, and Fridays; nystatin 5 mL 3 times a day (TID); lamivudine 100 mg daily; and valganciclovir 900 mg PO daily. Hepatitis B immunoglobulin (HBIG) 10,000 IU was started intraoperatively and given every day for 8 days after transplantation. What is the rationale for the aforementioned agents? Should other measures be considered to prevent infection?

Infection continues to be a major source of morbidity and mortality. Transplant recipients have the same risk of infection from transplant surgery as any other patient having a surgical procedure. The incidence of infections or organ transplant recipients has decreased since the advent of cyclosporine. Infection rates, however, remain high—upwards of 50% in transplant recipients.[79]

Prophylactic antimicrobial therapy decreases the risk of surgical infections; however, prophylactic regimens and antibiotic therapies are highly institution-dependent.[80] Kidney transplant recipients typically receive a first-generation cephalosporin, such as cefazolin, to cover uropathogens and staphylococci. Usually, antibiotic prophylaxis is given preoperatively, prior to skin incision and continued for one to three doses post-transplant. Due to how severely ill a cirrhotic is going into transplant and the fact that the surgery requires multiple anastomoses in an nonsterile environment (the bowel), liver transplantations are associated with the highest rate of life-threatening bacterial infection. Piperacillin–tazobactam commonly is used to cover staphylococci, enterococci, and Enterobacteriaceae. Duration of therapy in these patients is individualized, based on the patient's postoperative recovery, but usually lasts from 24 for 96 hours post-transplant.[80] Infections can occur at any time after transplantation, but there are predictable time patterns for certain kinds of infections.[79] The time of highest risk for infection in transplant recipients is during the first 6 months, because they are receiving the highest doses of immunosuppressive agents during this period. Another time of high risk is during and after treatment of acute rejection with high-dose immunosuppression. Patients can acquire new infections (Pneumocystis jiroveci pneumonia [PJP], CMV), reactivate old infections (e.g., CMV, BK virus), or experience recurrence of underlying disease (hepatitis B or C). Opportunistic infections are common during this time, as shown in Table 34-3. Because the infections shown in Table 34-3 occur at such a high rate, it is routine to provide specific prophylaxis for many of them. For example, nystatin suspension 500,000 IU by "swish and swallow" 3 to 4 times a day is commonly used for 1 month post-transplant in kidney recipients, and fluconazole 100 mg every day is used to reduce fungal colonization of the GI tract in liver and pancreas transplant recipients; acyclovir, ganciclovir, valacyclovir, valganciclovir, and immunoglobulins can be used for CMV and/or herpes virus infections; and TMP–SMX is used for Pneumocystis prophylaxis. For patients with sulfa allergies, alternatives, such as dapsone 50 to 100 mg PO daily, inhaled monthly doses of pentamidine 300 mg and atovaquone are used. These generally are given for the first 3 to 6 months after transplantation and, in some cases, up to 1 year or even for life.[81] S.C. needs prophylaxis with TMP–SMX for PJP prevention; valganciclovir for CMV prevention; and HBIG and lamivudine, adefovir, entecavir, tenofovir, or telbivudine to prevent recurrence of hepatitis B.

Table 34-3

Common Opportunistic Infections After Transplantation

Organisms	Usual Time of Onset After Transplantation
Cytomegalovirus	1–6 months

Herpes simplex virus	2 weeks–2 months
Epstein–Barr virus	2–6 months
Varicella-zoster virus	2–6 months
Fungal	1–6 months
Mycobacterium	1–6 months
Pneumocystis jiroveci pneumonia	1–6 months
Listeria	1 month–indefinitely
Aspergillus	1–4 months
Nocardia	1–4 months
Toxoplasma	1–4 months
Cryptococcus	4 months–indefinitely

Hepatitis B

A major concern for S.C. would be recurrence of hepatitis B in his new liver. If hepatitis B recurs, it is associated with a poorer outcome. Strategies that have been effective are the use of lamivudine, adefovir, entecavir, telbivudine, and tenofovir preoperatively and HBIG, with or without oral antiviral therapy, postoperatively. S.C. was started on lamivudine and HBIG postoperatively because monotherapy with HBIG is associated with recurrence in 10% to 50% patients, whereas HBIG with lamivudine has been associated with a lower incidence of recurrence compared to HBIG monotherapy. Lamivudine resistance rates are reported in 15-30% of patients taking this agent per year. In patients who develop a resistant form of hepatitis B to lamivudine, adefovir, entecavir, telbivudine, and tenofovir have been shown to be effective. After the first week of HBIG, S.C. will continue to receive 10,000 IU IV as a 1-hour to 2-hour infusion weekly for 4 weeks, then 10,000 IU monthly for the first 6 to 12 months after transplantation. During this time, anti-HBs titers are monitored and kept greater than 500 IU/L. Because HBIG is expensive (up to $50,000 per patient per year) and with the newer, more potent, oral antivirals available, more transplant centers now target lower titers (>100 IU/L) and HBIG doses of 1,500 IU intramuscularly every 3 to 4 weeks with lamivudine.[82]

Hepatitis C

Another virus that is a major cause for concern is hepatitis C. Hepatitis C is currently the most common reason for liver transplantation, and recurrence of hepatitis C viral replication after transplantation is universal.[83] Overimmunosuppression can have a significant detrimental effect on this disease after transplantation. Survival rates are significantly lower at 5 years after transplant compared with patients who received liver transplants for non-hepatitis-C causes.[83] Recently, there have been dramatic advances in the treatment of hepatitis C, with the advent of noninterferon-based direct-acting antiviral (DAA) therapies. Preliminary studies have demonstrated sustained virologic response rates of >70%, as compared to rates of 30% to 50% with interferon-based therapies. In addition, the DAA therapies have a much improved tolerability profile, with less cytopenias and limited constitutional symptoms, thus substantially reducing the need to hold or discontinue therapy, as compared to interferon and ribavirin.[84,85]

Cytomegalovirus

CASE 34-10

QUESTION 1: A.A., a 58-year-old, 76-kg man with end-stage liver disease caused by alcoholic cirrhosis, received an orthotopic liver transplant 4 months ago. He presents to the transplantation clinic with a 7-day history of generalized malaise, fatigue, nausea, vomiting, diarrhea, low-grade fevers, and anorexia. At the time of transplantation, the liver he received was positive for CMV antibody, but he had negative CMV serology (CMV naïve). His postoperative immunosuppressant regimen included oral prednisone and tacrolimus 5 mg PO BID, with adjustments made to his dose to maintain a 12-hour trough concentration between 6 and 12 ng/mL. He was also given valganciclovir 450 mg PO daily for 3 months.

His postoperative course was complicated by an acute rejection episode on postoperative day 19, which was treated successfully with a pulse and taper of steroids. At that time, MMF 1 g PO BID was added to his immunosuppressant regimen. He was discharged from the hospital on postoperative day 24, with instructions to return to the transplant clinic in 4 days. Since then, he has done fairly well with no complaints until now, 4 months later. On admission to the hospital, a physical examination was remarkable for an oral temperature of 38.8°C, a BP of 112/79 mm Hg, a heart rate of 104 beats/minute, a respiratory rate of 22 breaths/minute, and a mild tremor. All other findings on his examination were benign. Pertinent laboratory findings include the following:

WBC count, 3,400 cells/μL
Platelet count, 34,000 cells/μL
BUN, 29 mg/dL
SCr, 1.4 mg/dL
Total bilirubin, 2.2 mg/dL
AST, 62 IU/L
ALT, 126 IU/L
CMV PCR 184,000 copies/mL (normal <500 copies/mL)
12-hour tacrolimus concentration, 18.3 ng/dL

His current medications include tacrolimus 6 mg PO BID; MMF 750 mg PO BID; prednisone 10 mg PO daily; TMP–SMX 80 mg PO Mondays, Wednesdays, and Fridays; calcium carbonate 1.25 g PO TID; vitamin D 800 IU PO daily; enteric-coated aspirin 325 mg PO daily; and nizatidine 150 mg PO BID. What is the most likely diagnosis for A.A.?

A major concern in A.A. at this time after transplantation is CMV infection, which is commonly encountered within 1 to 6 months after solid organ and bone marrow transplantation. It is a ubiquitous virus belonging to the herpes virus group. In healthy immunocompetent adults, infection with the virus is usually asymptomatic, whereas in immunocompromised patients, CMV can cause significant morbidity and mortality. CMV can potentiate the risk for developing bacterial and fungal infections and induce chronic injury to the transplanted organ (arteriosclerosis in the heart, obliterative bronchiolitis in the lungs, vanishing bile duct syndrome in the liver, and chronic arteriopathy in the kidneys).[86]

ETIOLOGY

Cytomegalovirus infection in transplant recipients usually occurs when latent viruses from a seropositive donor organ are reactivated owing to immunosuppression. Without prophylaxis, transmission of CMV from a positive donor to a negative recipient leads to an 80% to 100% infection rate and a 40% to 50% disease rate; a positive donor to a positive recipient leads to a 40% to 60% reactivation rate and a 20% to 30% disease rate; and a negative donor to a negative recipient leads to a 0% to 5% infection rate. Transplant recipients at highest risk for developing the disease are (a) those who are or have serologically positive donor and negative recipient (D+/R−) at the time of transplant, (b) elderly, (c) those who received antilymphocyte antibodies, (d) those who received a retransplantation because of acute rejection, and (e) those who received larger amounts of immunosuppressive agents.[86] A.A. is at high risk of CMV infection and disease because his CMV serology is D+/R−, he was treated for rejection, and his immunosuppression regimen is fairly intense for a liver transplant recipient.

DIAGNOSIS

Diagnosis of CMV is based on both clinical and laboratory findings. CMV may be detected by culturing body fluids, such as bronchoalveolar lavage, urine, blood, and tissue biopsies. CMV is contained within the host's leukocytes, which appear to have large intranuclear inclusion bodies. CMV PCR is now readily available with rapid turnaround in most centers for measuring viral loads in the patient's serum. Documented viral shedding alone is not, however, diagnostic for active disease without clinical signs and symptoms.[87] A.A. has laboratory findings consistent with CMV infection: viral shedding, as indicated by the CMV PCR of 184,000 copies/mL, leukopenia, thrombocytopenia, and clinical symptoms consistent with CMV infection, including malaise, fatigue, nausea, vomiting, diarrhea, and anorexia.

CLINICAL MANIFESTATIONS

In healthy immunocompetent adults, the CMV-infected individual is usually asymptomatic but may present with mild complaints of malaise, fever, and myalgias, as well as abnormal liver enzymes and lymphocytosis. More severe reactions are rare.[86,87] CMV may, however, be life-threatening in the immunocompromised. Evidence indicates that CMV infection is associated with graft rejection and that graft rejection in the setting of immunosuppression further exacerbates CMV infection. It often is unclear which comes first. The actual CMV course may be limited to fever and mononucleosis, or it may extend to organs presenting as pneumonitis, hepatitis, gastroenteritis, colitis, disseminated infection, encephalopathy, or leukopenia.

A.A.'s clinical presentation meets the criteria for CMV disease: viremia with clinical signs and symptoms. At this time, it is unclear whether or not A.A. has any end-organ involvement/disease. His liver enzyme concentrations are elevated, and he is having numerous GI symptoms (nausea, vomiting, diarrhea, and anorexia), which may be indicative of CMV hepatitis, CMV gastroenteritis, or CMV colitis, respectively. Alternatively, the increased total bilirubin and serum transaminases may be caused by acute rejection, and his GI problems and leukopenia may be a side effect he is experiencing from his medications (e.g., MMF). To fully differentiate among CMV hepatitis, CMV gastroenteritis, CMV colitis, acute rejection, and medication side effects, tissue biopsies should be obtained.

CASE 34-10, QUESTION 2: What are the treatment options for A.A.'s diagnosed CMV disease? What doses should be used, and how should the effects of these drugs be monitored?

Ganciclovir

Before ganciclovir was available, CMV infection was "treated" by reducing the level of immunosuppression. This may be one of the explanations for an increased prevalence of rejection associated with CMV infections. Graft loss in kidney recipients is undesirable; yet, it is not immediately life-threatening because a patient may return to dialysis. Reducing immunosuppression in liver recipients, however, could result in the patient's death owing to graft loss. Treatment has been largely unsuccessful with acyclovir, adenine arabinoside, and immune globulin. Ganciclovir is the first-line agent for the treatment of CMV disease in solid organ transplant recipients. Although ganciclovir is highly efficacious, there is still a potential 20% relapse rate of CMV after ganciclovir therapy in liver transplant recipients.

Ganciclovir, a virostatic agent, is a nucleoside analog that is phosphorylated in infected cells to its active form and is then incorporated into replicating viral DNA. Although ganciclovir-resistant strains of CMV have been isolated, their occurrence is far more common in patients with HIV; currently, ganciclovir-resistant CMV in solid organ transplantation is not a large concern. A.A. should receive ganciclovir IV, or oral valganciclovir for mild CMV disease; a recent study has demonstrated equivalence between IV ganciclovir and oral valganciclovir. Because relapses of CMV disease after treatment are of concern, some suggest that patients should be placed on maintenance therapy with valganciclovir or oral acyclovir after the IV course is completed.[88]

Dosing

In patients with normal renal function, the usual dose of ganciclovir is 5 mg/kg/dose every 12 hours and the usual dose of valganciclovir is 900 mg PO BID, both for 14 to 21 days. Dosage adjustment is necessary for patients with renal dysfunction with either agent. Because A.A. has an estimated creatinine clearance of 60 mL/minute, he should receive 2.5 mg/kg/dose (190 mg) IV every 12 hours for 2 to 3 weeks, followed by maintenance valganciclovir 450 mg PO daily for 2 to 4 weeks.

The most common adverse effect associated with ganciclovir therapy is neutropenia, occurring in up to 27% of patients.[87] Neutropenia is defined as an absolute neutrophil count of less than 500 to 1,000 cells/μL. The neutropenia usually resolves with a decrease in dosage or discontinuation of the drug, but colony-stimulating factors increase the total white count.[88] Because CMV disease has a propensity to cause neutropenia as well, it is often difficult to distinguish the cause. If laboratory findings and clinical signs and symptoms of CMV disease are resolving and the patient remains neutropenic, the most likely cause is ganciclovir. Thrombocytopenia occurs in approximately 20% of ganciclovir recipients. Patients with initial platelet counts less than 100,000/μL appear to be at greatest risk. Other adverse effects include CNS effects, fever, rash, and abnormal LFT findings.[86,87] A.A.'s WBC with differential and platelet counts should be assessed every 3 to 4 days during therapy, and ganciclovir should be held if neutrophils fall to less than 500/μL or platelets fall to less than 25,000/μL. To monitor either the regression or progression of A.A.'s CMV disease, a weekly serum CMV DNA PCR should be obtained.

Immunoglobulins

The use of immunoglobulins to treat CMV disease in solid organ transplantation is controversial. They are expensive and sometimes in short supply. Immunoglobulins provide passive immunization by potentiating an antibody-dependent, cell-mediated cytotoxic reaction. Basically, the immunoglobulins modify the immunologic response that damages host tissue. Some evidence suggests that immunoglobulins may have synergistic or additive effects with current antiviral drugs in the treatment of CMV disease.[88] Both unselective immunoglobulins and CMV hyperimmune globulin have been studied in combination with ganciclovir. CMV hyperimmune globulin is prepared from high-titer pooled sera that have a fourfold to eightfold enrichment of CMV titers compared with unscreened immunoglobulin.

Cytomegalovirus immunoglobulin may be given as 100 mg/kg/dose every other day for 14 days. This is the dose recommended for treatment of CMV when used in combination with ganciclovir. The most common adverse effects associated with the administration of immunoglobulins are infusion related and include fever, chills, headache, myalgia, light-headedness, and nausea and vomiting.

Foscarnet

Foscarnet is a virostatic pyrophosphate analog that inhibits DNA synthesis; however, unlike ganciclovir, no phosphorylation is required for activation. Because this drug has a high nephrotoxicity propensity and because most transplant recipients are already receiving drugs that are nephrotoxic, experience with the use of foscarnet in solid organ transplantation is limited. In most centers, foscarnet is a second-line or third-line agent to be used only if intolerance or resistance develops with ganciclovir therapy.

The usual dosage of foscarnet is 60 mg/kg/dose every 8 hours for 14 to 21 days. The dosage should be reduced in patients with renal dysfunction. The most serious adverse effect with foscarnet is nephrotoxicity, which occurs in up to 50% of patients and is probably induced by acute tubular necrosis. Therefore, prehydration is suggested to help minimize or avoid nephrotoxicity. GI effects, a decrease in hemoglobin and hematocrit, an increase in LFTs, and alteration of serum electrolyte concentrations are other side effects of foscarnet. All of these appear to be reversible on discontinuation of the drug. SCr should be monitored daily during therapy.[87]

PROPHYLAXIS

CASE 34-10, QUESTION 3: Is there any way to prevent CMV in high-risk patients such as A.A.?

Because of its significant consequences, efforts should be made to prevent CMV disease. Many studies have tried to ascertain the easiest, most cost-effective regimen to prevent CMV disease.

These studies have focused on the combined use of different agents as well as IV followed by oral therapies. Trials have also targeted high-risk patients and assessed the use of CMV PCR monitoring, without the use of universal prophylaxis therapy (preemptive strategy).[88]

Ganciclovir

The use of both the IV and oral formulations of ganciclovir to prevent CMV disease has been studied in liver and kidney recipients.[89] Very few large trials have been conducted, and most of the data in the solid organ transplantation population are from small uncontrolled trials. Another difficulty lies in that large discrepancies exist between the trials with regard to the terminology used to define prophylaxis and high-risk patients. Until the introduction of valganciclovir, ganciclovir was the most widely used prophylactic agent.

In the United States, oral ganciclovir therapy has not been commercially available for a number of years. Thus, most transplant centers are now solely using valganciclovir therapy as their first-line agent. IV ganciclovir is still available and can be used for short periods if the patient is not able to tolerate oral therapy.

Valganciclovir

Valganciclovir was developed because oral ganciclovir has a very low bioavailability (<10%). Valganciclovir is the L-valyl ester of ganciclovir, which is a prodrug that is rapidly and completely converted into ganciclovir by hepatic and intestinal esterases once absorbed across the GI tract. The absolute bioavailability of valganciclovir is approximately 60%, so that a 900-mg single PO dose given with food is an AUC equivalent to a 5 mg/kg IV dose of ganciclovir. This is roughly twice the AUC achieved by 1,000 mg of ganciclovir given orally TID. Valganciclovir is currently FDA-approved for the treatment of HIV-associated CMV retinitis and to prevent CMV disease in heart, kidney, and pancreas transplantation.[90,91] Valganciclovir is not FDA-approved for prevention of CMV disease in liver transplantation, although it is often used in such cases. Several small studies have demonstrated that valganciclovir is effective in treating CMV infection preemptively and potentially preventing CMV disease.[90]

Because valganciclovir is very expensive and has a high potential for causing hematologic toxicities, several studies have been conducted using reduced dosing strategies. Most use half the recommended dose of 900 mg PO daily in patients with good renal function and have shown equivalent clinical outcomes with the potential of reducing cost and toxicities. These studies were conducted in kidney transplant patients, and the dosing of this agent is transplant center-specific based on institutional protocols.[92]

Valacyclovir

One published meta-analysis of 12 trials that included 1,574 patients evaluated valacyclovir as a prophylactic agent in transplant recipients.[93] Valacyclovir was found to be more effective than acyclovir in preventing herpes viruses, including CMV. Most transplantation centers, however, do not use valacyclovir for routine prophylaxis of CMV, and still consider valganciclovir first line.

Cytomegalovirus Hyperimmune Globulin

The role of CMV hyperimmune globulin in preventing CMV disease is controversial. Many studies have combined this agent with either oral acyclovir or ganciclovir, but because of its high cost and IV route, its use as a prophylactic agent has decreased. In addition, in patients who are D+/R−, results have been mixed.[87,94]

CASE 34-10, QUESTION 4: Should A.A. have received prophylactic therapy and, if so, which agent should be used?

A.A. has several risk factors that predispose him to developing CMV disease. At the time of transplantation, A.A. was CMV D+/R−, which means that he has about an 80% chance of developing CMV infection and a 40% chance of developing CMV disease. In addition, A.A. had an early acute rejection episode, which means he received higher doses of immunosuppression, also putting him at higher risk for developing CMV disease. Because of these risk factors, A.A. should have (and did) receive CMV prophylaxis for at least 3 months after transplantation. Some centers may extend prophylaxis to 6 months post-transplant in patients like A.A. A.A. developed CMV disease and is being treated with ganciclovir 190 mg every 12 hours IV. Once A.A. is tolerating oral medications, he can start receiving oral valganciclovir at a dose of 900 mg twice daily with food. Because A.A. has renal insufficiency, his oral valganciclovir dose will be adjusted to 450 mg daily.[92]

Cytomegalovirus Resistance to Anti-viral Therapies

Although uncommon, CMV resistance to anti-viral therapies, as defined by continued viral replication despite prolonged treatment, may be present in 5% to 12% of patients that have a high-risk serostatus (D+/R−). There have been two primary gene mutations associated with this resistance, one to the UL97 kinase and the other to the UL54 DNA polymerase gene. The vast majority (90%) of resistant strains to ganciclovir contain mutations to the UL97 gene, which usually does not confer cross-resistance to other anti-viral therapies, including cidofovir or foscarnet.[95]

As illustrated by A.A.'s case, a patient who has received prophylactic therapy does not preclude the development of CMV disease after the prophylaxis is withdrawn or, in rare instances, during prophylactic therapy. The incidence of CMV disease while receiving valganciclovir is significantly lower when compared to oral ganciclovir, probably because drug exposure is approximately 2 times higher.[90–92]

Preemptive Therapy

Because of recent advances in the laboratory tests used to identify and quantify CMV; because prophylactic therapy is not always effective; and because it is often toxic and very expensive, preemptive therapy has also been used to prevent CMV disease. The technique involves withholding prophylactic therapy and monitoring laboratory tests to identify presymptomatic CMV viremia, usually by using serum CMV DNA PCR. Once a patient develops viremia (CMV PCR viral load >2,000 copies/mL), he/she receives treatment with IV ganciclovir or oral valganciclovir. This strategy has been prospectively studied and is as effective as universal prophylaxis, with some potential cost advantages. However, a few recent studies have demonstrated a higher incidence of the indirect effects of CMV in the preemptive group—most-concerning in one study, graft loss. Thus, the preemptive therapy role is controversial, with many centers still using universal CMV prophylaxis in all solid organ transplant recipients.[88]

Post-transplantation Lymphoproliferative Disorder

RISK FACTORS

CASE 34-11

QUESTION 1: A.L., a 16-year-old, 42-kg girl, underwent liver transplant 1 year ago secondary to biliary atresia with a failed Kasai procedure. She now presents with low-grade fever, malaise, pain, and a 1-week history of decreased appetite. She has experienced two episodes of rejection that were treated with 1 to 2 g of methylprednisolone each time, with the last rejection episode requiring rabbit antithymocyte globulin therapy. She received tacrolimus and prednisone after transplantation and had MMF added to her immunosuppressant regimen after the second rejection episode. She has just finished a course of IV ganciclovir (4 weeks) for CMV infection. The donor was CMV-positive, and she is CMV-positive. Her EBV DNA PCR is now 18,000 copies/mL (normal, <500 copies/mL); this value was negative at the time of transplant, but because her last rejection episode has been increasing in value. On physical examination, she was noted to have mediastinal adenopathy. She denies chills, sweats, nausea, vomiting, or diarrhea. A chest computed tomography scan revealed a mediastinal mass. Vital signs and all laboratory tests are within normal limits. Her tacrolimus trough is 9.8 ng/mL. Seven days after admission, a biopsy of this mass shows a thoracic lymphoproliferative lesion identified as a thoracic immunoblastic lymphoma adherent to the right side of the heart. Ten days later, she developed tachy/brady syndrome and a pacemaker was implanted. Given the location of her lymphoma and symptoms, surgery and radiation therapy are not viable options, and chemotherapy is started the next day. What clinical signs and risk factors in A.L. are associated with lymphoma?

A.L. has developed a PTLD, one of many types of malignancies that have been reported after solid organ transplantation. The exact etiology of this condition is unclear and probably multifactorial. The presentation of PTLD varies significantly. Patients can present asymptomatically, with mild mononucleosis-like symptoms or with multiorgan failure. A.L. presents with fever, lymphadenopathy, malaise, and lack of appetite. Although these symptoms are consistent with PTLD, they also are consistent with infection. Because PTLD can involve various organ systems, patients can present with organ-specific symptoms (e.g., acute abdominal pain, perforation, obstruction, bleeding if a tumor is in the GI tract). Depending on its location, a tumor can impinge on the function of other organs, as seen in A.L.[96] Besides immunosuppression, two factors that have been strongly associated with PTLD are the presence of EBV and the age of the patient. Children have a higher incidence of PTLD.[97] A.L. developed EBV DNA viremia, indicating that she had been exposed to this virus at the time of transplantation or afterward. EBV also can be transmitted from the donor liver and/or blood products. Also, EBV-positive recipients at the time of transplantation can experience reactivation of this virus as a result of immunosuppression.

A.L. received a significant amount of immunosuppression. This could lead to an inability to suppress an active viral infection by cytotoxic T cells and result in uncontrolled B-cell proliferation and polyclonal and monoclonal expansion. In addition to this T-cell defect, an imbalance or alteration in cytokine production in response to EBV, which infects B lymphocytes, may contribute to the exaggerated B-cell expansion and transformation; most are classified as non-Hodgkin lymphomas primarily of B-cell origin. Small percentages are of T-cell origin, however, and are harder to treat.[96] The incidence and detection of PTLD has increased. Newer, more potent immunosuppressive agents used in different combinations, increased numbers of transplantation procedures, and closer monitoring contribute to this phenomenon. When cyclosporine-based regimens were compared with azathioprine or cyclophosphamide-based regimens, lymphomas made up 26% and 11% of all cancers, respectively. The lymphomas occurred, on average, within 15 months after transplant in the cyclosporine group versus 48 months in the azathioprine group. One-third of these malignancies occurred in the first 4 months in the cyclosporine group compared with only 11% in the latter group.[96]

The incidence of PTLD increases with rabbit antithymocyte globulin therapy and appears to be related to a cumulative dose and multiple courses. PTLD is not caused by any single agent but probably reflects the intensity of immunosuppression with multiple agents. Chronic antigenic stimulation by foreign antigens, repeated infections, genetic predisposition, and indirect or direct damage to DNA are other variables that might affect the development of PTLD.[98] A.L. had a recent CMV infection, which also could have contributed to this process.

As a percentage of all malignancies, PTLD occurs more commonly in thoracic than in other types of solid organ transplants and is even more common in children. Lymphomas develop in about 1% of kidney transplantations and 2% of liver transplantations. These tumors often appear early and progress rapidly. The overall prevalence of malignancies in the transplantation population averages about 6%, and the risk of cancer increases with time after a transplantation. Major organ transplant recipients are 100 times more likely to have cancer than the general population. Furthermore, the most common types of cancer observed in transplant recipients (e.g., lymphomas, cancer of the skin and lips) are uncommon in the general population. The development of skin and lip cancers in the transplant population has been attributed partially to exposure to sunlight and sensitization of skin to sunlight by an azathioprine metabolite, methylnitrothioimidazole.[96]

TREATMENT AND OUTCOMES

CASE 34-11, QUESTION 2: What are the therapeutic maneuvers and outcomes that would be expected in A.L.?

Treatment of a PTLD depends on timing, presentation, symptoms, extent of involvement, histologic type, and transplant type. Early experiences with PTLD indicated that reduction or discontinuation of immunosuppression led to regression of the cancer. Therefore, the first step in treating PTLD is to consider the discontinuation of all immunosuppressives, with the potential exception of the corticosteroids. This course of action is not feasible for A.L., however, because her transplanted liver is essential for her life. Immunosuppressive drugs can be discontinued in kidney recipients because dialysis can be reinstituted. A.L. will need chemotherapy for her cancer. Therefore, her MMF probably should be discontinued to minimize the potential for severe bone marrow toxicity. Additionally, A.L. will likely have a small reduction in her tacrolimus doses, with the goal of achieving trough concentrations on the lower end of her therapeutic range (4–6 ng/mL); her prednisone should also be reduced to the lowest dose possible. If her immunosuppressive drug therapy is diminished, she should be monitored closely for rejection.[99]

Antiviral therapy with IV acyclovir or ganciclovir has been used to inhibit EBV replication in an effort to treat PTLD. Response is variable and may depend on the type and extent of PTLD. A.L. already has received ganciclovir for 4 weeks during which time she presented with PTLD. Surgery, radiation therapy, and chemotherapy are used to treat PTLD depending on the situation. Interferon and immunoglobulin have been effective in a few cases that appeared unresponsive to other therapies. Monoclonal or immunoblastic, disseminated, rapidly progressive PTLD responds poorly to traditional therapy and has a mortality rate as high as 70%. Rituximab (an anti-B-cell, anti-CD20 antibody) is considered first-line therapy for CD20-postive B-cell PTLD along with reduction or withdrawal of immunosuppression if possible. Patients usually get 375 mg/m^2 weekly for 4 weeks; some groups have used prolonged therapy. Patients may have relapse or disease progression that may respond to chemotherapy regimens such as cyclophosphamide, adriamycin, vincristine, prednisone, or dexamethasone (CHOP); CHOP plus rituximab (CHOP-R); and cyclophosphamide, doxorubicin, etopside, prednisone, cytarabine, bleomycin, vincristine, and methotrexate (PROMACE-cytaBOM).

Transplant recipients have a higher risk of myelotoxic side effects, depending on their maintenance immunosuppression. A.L.'s prognosis is poor given the type and extent of her PTLD, which would have been more responsive to therapy if it had been diagnosed early. Polyclonal PTLD responds well to reduction or discontinuation of immunosuppression and high-dose acyclovir or ganciclovir therapy for several weeks to months. The roles of prophylactic antivirals, immunoglobulins, and EBV PCR monitoring in the prevention of PTLD are currently controversial, with mixed results in current literature.[99]

SECTION 7 | Nutrition Issues

Section Editors: R. Rebecca Couris and Susan L. Mayhew

35

Basics of Nutrition and Patient Assessment

Jeff F. Binkley

CORE PRINCIPLES	CHAPTER CASES
1 A complete nutritional assessment of the patient is imperative before specialized nutrition is initiated. Parameters to be considered are nutrition and weight history, physical examination, anthropometric and biochemical measurements, and malnutrition risk.	**Case 35-1 (Question 1)**
2 The nutritional status of a patient can be assessed using the subjective global assessment (SGA) technique, which has been found to be highly predictive of outcome, because the SGA correlates strongly with other subjective and objective measures of nutrition.	**Case 35-1 (Question 1)**
3 Patients who cannot meet their nutritional needs by consuming food orally should be considered for specialized nutritional support, which is the provision of parenteral or enteral nutrients.	**Case 35-1 (Question 2)**
4 Protein and calorie goals are assessed on the basis of the disease status and body weight of the patient.	**Case 35-1 (Question 3)**
5 Nutritional support regimens should be tailored on the basis of the requirements, response, and tolerance of the patient. Patients with inflammatory bowel disease are particularly at risk for developing vitamin and other micronutrient deficiencies, and therefore, supplementation is warranted.	**Case 35-1 (Question 4)**
6 The fluid needs of a patient are determined by the following steps: (a) need to correct fluid imbalances, (b) maintenance fluid requirements, and (c) replacement of ongoing fluid losses.	**Case 35-1 (Question 5)**
7 Continued success of a nutritional support regimen can be accomplished by appropriate nutritional assessment after the initiation of therapy. The parameters such as patient weight trends, nitrogen balance, and prealbumin are considered when determining the need to adjust therapy.	**Case 35-1 (Question 6)**
8 Overfeeding should be avoided in patients, and a gradual and conservative approach to instituting nutritional support should be used to prevent potential metabolic abnormalities.	**Case 35-1 (Question 7)**

Recognition of the importance of adequate and appropriate nutrition is paramount to the maintenance of optimal health. When an imbalance exists between the supply and the demand for the sources of nutrients and energy by the body, a nutritional disorder can occur. Years of research and clinical experience have led to the creation of various screening tools, assessment techniques, and guidelines to aid practitioners in their quest to delay or prevent patients from developing dangerous sequelae associated with deviations from optimal nutrition.[1] Despite many advances in nutritional science, impaired nutritional status in developing nations continues to be a main cause of morbidity and mortality, especially in young children.

NUTRITION BASICS

Adequate levels of energy sources and essential nutrients are critical for retaining the structural and biochemical integrity of the human body. Energy is provided in the diet by macronutrients

---

such as carbohydrates, protein, and lipid. Essential nutrients, none of which offer any caloric value, are supplied to the body in the form of water, electrolytes, vitamins, and minerals.

Macronutrients

Humans need to consume food to sustain life. The unique structure and function of our cellular architecture allow human beings to convert the chemical free energy contained within the diet into high-energy, biologically active compounds. This transformation of food energy into forms of viable free energy through cellular respiration is an extremely inefficient process. Close examination of the distribution of food energy within the human body reveals that approximately 50% is lost as heat, 45% is available to the body in the form of adenosine triphosphate, and the remaining 5% is thermodynamically required for the conversion to heat because the entropy of the final products is greater than that of the initial substrates. Ultimately, all of the energy derived from food is expended in the form of external work or heat.

In nutritional contexts, the energy available from food is expressed in terms of the calorie. A calorie is technically defined by the amount of heat required to raise the temperature of 1 g of water by 1°C. This unit, however, is too small from a dietary perspective. A food calorie (sometimes written as Calorie with a large C, although this convention is not strictly followed) is equivalent to 1,000 calories or 1 kilocalorie (kcal). One food calorie is also equal to 4.184 kilojoules.[2] It is not uncommon for a single kilocalorie to be referred to as a calorie when communicating the energy content of food. This ambiguity must be understood by practicing clinicians to communicate properly not only with colleagues but also with patients and the general public who may not have an appreciation for this subtlety and remain confused when reading calories on nutrition labels yet and seeing kilocalories in textbooks, scientific publications, patient records, and Internet.

CARBOHYDRATES

Carbohydrates, also known as saccharides, are organic compounds that are chemically the hydrates of carbon. There are four main types of carbohydrates: monosaccharides, disaccharides, oligosaccharides, and polysaccharides. Dieticians frequently classify carbohydrates as either simple (monosaccharides and disaccharides) or complex (oligosaccharides and polysaccharides); yet, the exact delineation of these categories is often not clear. Although carbohydrates serve as a common source of energy for living organisms, these compounds also function as structural components and building blocks for complex genetic molecules.

Monosaccharides (e.g., glucose) are the simplest of carbohydrates and cannot be hydrolyzed into smaller saccharide molecules. They are the major sources of fuel, because glucose serves as a nearly universal and accessible reservoir of calories. In the context of food science, monosaccharides, collectively along with disaccharides, are commonly referred to as sugars and are found in foods such as candy and desserts. Natural sources of monosaccharides include fruits and vegetables, but these compounds are also found in commercially manufactured products such as high-fructose corn syrup. The latter is a common replacement for table sugar in processed foods composed of a high proportion of fructose relative to glucose.

Oligosaccharides are short chains of monosaccharides typically composed of 3 to 10 molecules linked through glycosidic bonds. These molecules are typically found connected to proteins or lipids functioning as chemical markers for cellular recognition. Their important role in the classification of blood groups is an example. Polymeric carbohydrate structures are referred to as polysaccharides and function either as storage forms of energy, such as glycogen in animals or starch in plants, or as a structural component, such as cellulose in plants. In humans, dietary polysaccharides must be catabolized to their constituent monosaccharides before absorption can occur.[3]

Dietary carbohydrates are composed of approximately 60% polysaccharides, mainly starch, and disaccharides such as sucrose and lactose, which represent 30% and 10%, respectively. All carbohydrates provide 4 kcal of energy/gram. Although the exact amount of dietary carbohydrates sufficient for good health is not known, a mixed-fuel diet in which carbohydrates constitute 45% to 65% of the total energy intake is considered an acceptable distribution range.[4]

PROTEIN

Polypeptides are linear chains of amino acids. These polypeptides can twist and fold alone or together into three-dimensional globular or fibrous structures, generating a biochemical compound known as the protein. Proteins are crucial to all living organisms and participate in a wide spectrum of processes. Many proteins function as enzymes, which serve as catalysts to biochemical reactions and are important for metabolism. Additionally, proteins can play a role in structure and function, such as actin and myosin in muscle—the largest source of protein in higher animals. Some proteins stabilize blood by giving it the appropriate viscosity and osmolarity, and yet, other proteins participate in cell signaling and immune responses.

Protein is the second largest store of energy in the body after adipose tissue.[5] Although protein differs from the other two primary dietary energy sources because of its inclusion of nitrogen, the amino acid residues from proteins can be converted to glucose via gluconeogenesis to supply a continuous source of glucose for the body after the depletion of glycogen. Like carbohydrates, each gram of protein supplies 4 kcal of energy. The loss of more than 30% of body protein, however, can compromise muscle strength, affect respiratory function, and negatively influence the immune system, all of which ultimately lead to organ dysfunction and death. It should be noted that protein and energy requirements of the body are intimately connected. During the times of infection or injury, metabolic rates rise and body protein is suddenly oxidized into amino acids and mobilized for fuel utilization. In most instances, the injuries that patients experience are minimal and self-limiting; however, patients with chronic illnesses or those with complicating factors that result in a long-term hypermetabolic state can subsequently experience a dangerous loss of body nitrogen.

LIPIDS

Lipids comprise a broad spectrum of molecular species ranging from hydrophobic triglycerides and sterol esters to hydrophilic phospholipids and cardiolipins, as well as dietary cholesterol and phytosterols. Biologic lipids function as a form of energy storage, serve as the structural components of cell membranes, and participate as messengers in the vital process of cellular signaling.

In a nutritional context, fats that exist as liquids at room temperature are typically called oils, whereas fats that remain solid at room temperature are labeled as fats. Although the term lipid is frequently used synonymously for fat, fats are actually a subgroup of lipids also known as triglycerides. Triglycerides are synthesized by chemically combining glycerol with three fatty acid molecules. These fatty acids are generally nonbranched hydrocarbons containing an even number of carbon atoms ranging from 4 to 26 carbons. Adipose tissue is composed of fatty acids in varying lengths.

An unsaturated fat is a fatty acid that includes at least one double bond within the fatty acid chain, and therefore, a saturated fat is one that contains no double bonds. Unsaturated fatty acids result in less energy after the oxidation process of cellular metabolism compared with an equivalent amount of saturated fatty acids. Commercial manufacturers of processed food favor saturated fats because they are less vulnerable to rancidity (lipid peroxidation) and remain solid at room temperature. Foods containing unsaturated fats include avocado, nuts, and vegetable oils such as canola and olive oils. Meat products contain both saturated and unsaturated fats.

Importantly, each gram of fat yields 9 kcal of energy, twice that of either carbohydrate or protein. Approximately 35% to 40% of the total daily calories consumed by the average human being are lipids. Higher-fat diets can lead to more rapid weight gain, a positive attribute if the individual is malnourished or underweight, but a negative attribute if the individual is trying to achieve weight loss.[6] Triglycerides make up by far the largest proportion of dietary lipids consumed by humans. Although humans possess the biologic pathways to synthesize lipids, there are two essential lipids that must originate from the diet to prevent essential fatty acid deficiency—linoleic acid and α-linolenic acid.

Essential Nutrients—Water

Water plays a critical role in nearly every biologic function necessary for life. The total body water in an adult male without fluid and electrolyte disorders is approximately 50% to 60% of the lean body weight.[7] Infants and children possess a much higher fractional water content, which then decreases progressively with age. Individuals with a greater percentage of body fat, such as women or obese patients, also tend to have less water for a given weight.

The total aqueous volume in the body can be divided into the intracellular and extracellular compartments. Because the intracellular fluid is the site of major metabolic activity, homeostatic mechanisms are therefore in constant execution to provide an environment of optimal ionic strength. The primary function of the extracellular fluid is to serve as a conduit between cells and between organs. Substantial ionic alterations within extracellular fluid can occur without a clinically significant impact on body function. This extracellular compartment can be further divided into three fractions: the interstitial volume, plasma volume, and transcellular water volume. Interstitial fluid flows around cells, allowing the total surface area of a cell to serve as an area of exchange. Plasma is the route for rapid transit within the body. Transcellular water is the smallest component of extracellular fluid and is the portion of total body water that can be found contained within epithelial-lined spaces. Transcellular water includes the luminal fluid of the gastrointestinal (GI) tract, the fluids of the central nervous system, and the fluid in the eye, as well as the lubricating fluids at serous surfaces.

The basal requirement of water for a given individual is dependent on the sensible (urinary) and insensible losses of water. Urine osmolality and the total amount of solute excreted from the body dictate the volume of water comprising urine. Fever can promote dehydration by increasing one's basal metabolic rate in addition to raising the vapor pressure of expired air and sweat, resulting in higher respiratory and skin water losses, respectively. In the absence of fever and sweating, water loss through the skin is relatively fixed; however, urinary water excretion can vary greatly.

Essential Nutrients—Micronutrients

ELECTROLYTES

A subtle and complex balance of electrolytes exists between the intracellular and extracellular milieu. The precise maintenance of these electrolyte gradients is critical as such gradients regulate hydration and pH and ultimately have an impact on nerve and muscle function. Sodium, chloride, and bicarbonate are the main solutes in the extracellular fluid, whereas potassium, magnesium, phosphate, and proteins are the dominant solutes inside the cell.

Although water can freely travel across the membrane of a cell, the cell membrane itself is only selectively permeable to solutes. Osmotically active solutes are those that are impermeable and thereby exert an osmotic pressure by which the distribution of water between fluid compartments is determined.

Electrolyte balance is traditionally maintained by the oral intake of substances containing electrolytes. Foods such as fruit juices, sports drinks, milk, and many fruits and vegetables are replete with electrolytes. In oral rehydration therapy, electrolyte drinks containing sodium and potassium salts replenish the water and electrolyte levels in the body after dehydration caused by exercise, excessive alcohol consumption, diaphoresis, diarrhea, vomiting, intoxication, or starvation. Hormones, such as antidiuretic hormone, aldosterone, and parathyroid hormone, regulate electrolytes once in the body, and the kidneys function to flush out those excess ions.

VITAMINS

Vitamins are organic compounds that cannot be biologically synthesized in sufficient quantities by human beings and yet remain a vital requirement for the sustainment of life. The biochemical functions of vitamins are diverse. Some vitamins assist in the regulation of electrolyte metabolism, whereas others participate in the control of cell and tissue growth and differentiation. Most vitamins function as cofactors, which are molecules that bind to enzymes to promote their catalytic activities.

Vitamins are classified by their biologic and chemical activity. Vitamins are designated as either water-soluble or fat-soluble. There are four fat-soluble vitamins (A, D, E, and K) and nine water-soluble vitamins (eight B vitamins and vitamin C) in humans. Water-soluble vitamins are used by the body quite rapidly, and amounts in excess are readily excreted from the body in urine. The fat-soluble vitamins are absorbed by the body using processes that closely parallel the absorption of lipids. Fat-soluble vitamins are more likely to lead to toxicity, or hypervitaminosis. Fat-soluble vitamin regulation is also of particular significance in cystic fibrosis.

Vitamins are procured through the diet or supplements. The body can manufacture only three vitamins from nondietary sources: vitamins D and K, and the B vitamin, biotin. Critically ill patients experiencing metabolic stress possess vitamin needs that may increase dramatically. Many disease states such as inflammatory bowel disease, liver and renal disease, short-bowel syndrome, cancer, and acquired immunodeficiency syndrome-associated wasting can also result in a higher demand for vitamins. A parenteral formulation of multivitamins combining both fat- and water-soluble vitamins into an aqueous solution designed for incorporation into intravenous infusions is available for these classes of patients.

TRACE ELEMENTS

Appropriate intake levels of certain dietary minerals have been demonstrated to be required in small amounts to maintain optimal health. These dietary minerals are known as trace elements or ultratrace elements. Iron, zinc, copper, manganese, and fluoride are classified as trace elements. These minerals are required in amounts between 1 and 100 mg/day by adults. Ultratrace elements, or those dietary minerals that are required in quantities less than 1 mg/day, include arsenic, boron, chromium, iodine, selenium, silicon, nickel, and vanadium.

Consuming specific foods rich with the dietary mineral of interest is the recommended method for satisfying these micronutrient requirements. Many trace elements are naturally present in foods; however, some are added to foods to prevent nutrient deficiencies—such as fortifying salt with iodine to prevent development of hypothyroidism and goiter. When dietary intake is insufficient to meet the daily nutrient requirements of an individual or when chronic or acute deficiencies arise from pathology and injury, dietary supplements remain a viable option. Supplements can be formulated to include multiple trace elements, a combination of vitamins, or a single trace element.

MALNUTRITION

Malnutrition may occur when there is any disruption of nutritional status, including disorders resulting from overfeeding or underfeeding or through impaired nutrient metabolism. Clinically, a more useful definition of malnutrition is the state induced by alterations in dietary intake, which results in subcellular, cellular, or organ function changes that expose the individual to increased risks of morbidity and mortality and can be reversed by adequate nutritional intervention.[8] An incidence of malnutrition as high as 30% to 50% has been reported among hospitalized patients.[9,10] In these hospitalized patients, the risk of acute malnutrition development is greater because nutrient intake is often inadequate, nutrient stores can be depleted, or the patients may experience concurrent injury or stress (e.g., trauma, infection, major surgery). The presence of acute stress or injury increases energy requirements to repair tissues. Breakdown of skeletal muscle to release amino acids for energy production by conversion to glucose occurs if exogenous energy is not provided to stressed patients. Even patients who were well nourished before the stressful event may quickly become at risk for this type of iatrogenic malnutrition. Usually conditional, acute malnutrition resolves once the illness or injury improves and normal nutrient intake is resumed.

In stark contrast to stress-induced malnutrition, patients in starvation or semistarvation states slowly adapt to inadequate nutrient intake. In this scenario, endogenous fat stores are used for energy and a slow loss of muscle proteins ensues. Nevertheless, energy and protein stores are not unlimited, and death occurs in previously normal-weight individuals after about 60 to 70 days of starvation.[11,12] Patients with a history of chronic malnutrition who are faced with stress or injury are at the greatest risk of developing malnutrition.

The most common type of nutritional deficiency in hospitalized patients is protein-calorie malnutrition, which includes depletion of both tissue energy stores and body proteins. Complications develop more frequently for hospitalized patients who are malnourished as a result of organ wasting and functional impairments. These complications may include weakness, decreased wound healing, altered hepatic metabolism of drugs, increased respiratory failure, decreased cardiac contractility, and infections such as pneumonia and abscesses. Complications often increase the length of hospital stay and costs of care, and may even ultimately reduce reimbursement for institutions.[13–15]

Malnutrition or its risk may occur in patients with inadequate intake for 7 to 14 days or in patients with an unintentional weight loss of 10% before their illness. For these patients, nutritional intervention is appropriate and should be considered.[16,17] Patients who cannot meet their nutritional needs by consuming enough food orally should be considered for an alternative nutrition mechanism. Specialized nutritional support is the provision of parenteral or enteral nutrients, which are specifically formulated or delivered to maintain or restore nutritional status.[18] For those who cannot eat by mouth but have a functional GI tract, the first line of nutritional intervention to be considered should be enteral feeding through an appropriate access device (see Chapter 37, Adult Enteral Nutrition, and Chapter 38, Adult Parenteral Nutrition).

To mimic the normal physiologic state when possible, the GI tract should be used for providing nutrients. Enteral nutrients may be more beneficial and are generally less costly than those provided by the parenteral route.[19] Enteral nutrients stimulate the intestine, thus maintaining the mucosal barrier structure and function. This has been associated with decreased infectious morbidity in critically ill patients compared with those receiving nutrients parenterally.[20–24] Parenteral nutrition is therefore reserved for patients whose GI tracts are not functional or cannot be accessed, or who do not absorb enough nutrients to maintain adequate nutritional status.[16]

NUTRITION SCREENING

According to The Joint Commission (http://www.jointcommission.org), hospitals are required to screen patients within 24 hours of admission to determine whether they are malnourished or at risk for developing malnutrition. The nutrition screening process identifies needs for further nutritional intervention or monitoring based on nutritional risk. The information collected in the screening process is dependent on the patient population, the healthcare setting, and individual institution policy. A number of screening tools have been described in the literature with varying reliability, specificity, and sensitivity. Some parameters included in nutrition screening may have wider applicability in the outpatient setting than in the inpatient arenas.[1,9]

Patient Assessment

Nutritional assessment of a patient incorporates a collection of historical data, analysis of body composition, evaluation of physiologic function, and complete physical examination. Proper patient assessment should include the examination of multiple factors and should not rely on any one parameter. This assessment serves to identify the presence and severity of malnutrition or the risk of developing malnutrition. A complete patient assessment performed by a trained practitioner can help determine the goals of therapy and specify the need for specialized nutritional support. Goals of therapy may be maintenance of existing nutritional status, repletion of fat and lean body mass, and prevention of complications associated with malnutrition.

NUTRITION HISTORY

A nutrition history is crucial in an effective nutritional assessment. Practitioners may gain valuable information by interviewing the patient or the patient’s family and by reviewing the medical record to identify factors that can contribute to malnutrition or increase the risk of developing malnutrition.

Multiple factors can contribute to the development of malnutrition, including the patient's underlying disease states, past medical history, and socioeconomic circumstances. Medications can adversely affect nutritional status by decreasing the synthesis of nutrients, minimizing food intake through alteration of appetite and taste, changing the absorption or metabolism of nutrients, or increasing nutrient requirements. A complete evaluation of present and past body weight habits contributes significantly to an appropriate nutrition history.

The components of a nutrition history are summarized in Table 35-1, some of which are expanded subsequently.

WEIGHT HISTORY

Weight history and influences are important in evaluating nutritional status. Weight loss is a sign of negative energy and negative protein balance and is often associated with poor outcome in hospitalized patients.[9,25] A patient's current weight often is compared with a standard for ideal body weight (IBW). Percentage of IBW[9] is determined as shown in Eq. 35-1:

Table 35-1

Components of a Nutrition History

Medical history
Chronic illnesses
Surgical history
Psychosocial history
Socioeconomic status
History of gastrointestinal problems (nausea, vomiting, or diarrhea)
Diet history, including diets for weight gain or loss
Food preferences and intolerances
Medications
Weight history
Increase or decrease
Intentional or unintentional
Time period for weight change
Functional capacity

$$\%\ \text{IBW} = \text{Current weight}\ (100)/\text{IBW} \qquad \text{(Eq. 35-1)}$$

The primary limitation of this method of assessing weight is that the patient's weight is compared with a population standard rather than using the individual as the reference point. For example, a patient who is significantly overweight but has lost large amounts of weight may still be more than 100% of IBW and therefore not considered at risk for developing malnutrition. A more patient-specific method of evaluating weight is to compare current weight with the patient's usual weight. This can be determined using Eq. 35-2:

$$\%\ \text{Usual body weight} = \text{Current weight}\ (100)/\ \text{Usual body weight} \qquad \text{(Eq. 35-2)}$$

Using this method, the obese patient who has lost weight may be determined to be less than 90% of usual weight and therefore nutritionally at risk. It is also important to assess over what time period the change has occurred. Involuntary weight loss is considered severe if loss exceeds 5% of usual weight within 1 month, or 10% of usual weight within 6 months. A nonvolitional weight loss of more than 10% is considered significant for malnutrition.[18] Patterns of weight loss must be evaluated to determine whether the loss is stabilizing or continual, the latter being a more serious concern. Weight gain after a significant weight loss may be considered a positive sign.

PHYSICAL EXAMINATION

Nutritional deficiencies may be identified on physical examination, and these findings may require further evaluation. Muscle and fat wasting (often noticed in the temporal area), loss of subcutaneous fat and muscle in the shoulders, and loss of subcutaneous fat in the interosseous and palmar areas of the hands are readily identifiable. Other physical parameters that may be less obvious are assessment of hair for color changes and sparseness, skin for turgor, pigmentation, and dermatitis, mouth for glossitis, gingivitis, cheilosis, and color of the tongue, nails for friability and lines, and abdomen for signs of ascites or enlarged liver. Additionally, the patient's fluid status must be evaluated as a part of the physical examination.

ANTHROPOMETRICS

Anthropometry is the science of body composition based on measurement of weight, stature, body circumferences, and subcutaneous fat thickness. Physical examination may include measurement of subcutaneous fat and skeletal muscle mass. Assessment of fat stores provides information about fat loss or gain and assumes fat is gained or lost proportionally throughout the entire body. The subcutaneous compartment contains approximately 50% of body fat. Triceps skinfold and subscapular skinfold thickness measurements are methods used to assess subcutaneous fat, allowing associated estimations of total body fat.

Reference standards[26] are used to compare against values obtained in the examination. Somatic protein mass or skeletal muscle mass can be estimated by measuring mid-arm circumference and then calculating arm muscle circumference. These values are also compared with standards, and the amount of muscle mass is then estimated.

Anthropometric measurements accurately reflect total body fat and skeletal muscle mass when used for the long-term comparisons of large, nutritionally stable populations. However, anthropometric measurements of hospitalized patients are of little value. Changes experienced during acute illness and stress may result in errors of interpretation of subcutaneous fat and weight assessments, and peripheral edema can result in inflated values for skinfold thickness and mid-arm circumference.[9,25]

Biochemical Assessment

Biochemical assessment of nutritional status includes the examination of protein status. No single test or group of tests can be recommended as a routine or reliable indicator of protein status. It is a combination of measures—biochemical, anthropometric, dietary, and clinical findings—that produce a more complete picture of protein status.

The protein composition of the human body can be viewed as a two-compartment model—somatic and visceral proteins. Somatic proteins are those constituting skeletal muscle; they account for approximately 75% of total body protein. The remaining 25% of total body protein are visceral proteins, which are found in the internal organs and serum. Albumin, prealbumin, transferrin, and retinol-binding protein are the most common visceral proteins used to assess nutritional status. These proteins are produced by the liver and often reflect hepatic synthetic capability. When hepatic insufficiency develops or when intake of substrates is inadequate for synthesis of proteins, the serum concentration of visceral proteins decreases. During stress or injury, inflammatory cytokines are released and substrates are shunted away from the synthesis of these proteins to synthesize other acute-phase proteins such as C-reactive protein, haptoglobin, fibrinogen, and others.[27] Serum protein concentrations are altered during acute stress or inflammatory states and chronic starvation.[25,27]

Albumin is the classic visceral protein used to evaluate nutritional status and is a prognostic indicator. Serum concentrations of less than 3 g/dL correlate with poor outcome and an increased length of stay of hospitalized patients.[28] Albumin serves as a carrier protein for fatty acids, hormones, minerals, and drugs, and is necessary for maintaining oncotic pressure. Albumin has a large body pool of 3 to 5 g/kg, and 30% to 40% is localized to the intravascular space. The normal hepatic rate of albumin synthesis is 150 to 250 mg/kg/day. Because albumin has a half-life of 18 to 21 days, a decrease in serum albumin concentrations is generally not observed until after several weeks of inadequate nitrogen intake. Serum albumin concentrations decrease rapidly in response to stress (which causes albumin to shift from the intravascular to the extravascular space), burns, nephrotic syndrome, protein-losing enteropathy, overhydration, and decreased synthesis with liver disease.[25,27]

Table 35-2

Visceral Proteins for Nutritional Assessment

Visceral Protein	Half-Life (days)	Normal Serum Concentration
Albumin	18–21	3.5–5 g/dL
Transferrin	8–10	250–300 mg/dL
Transthyretin (prealbumin)	2–3	15–40 mg/dL
Retinol-binding protein	0.5	2.5–7.5 mg/dL

Transferrin, which is involved in the transport of iron, has a half-life of 8 to 10 days and is more sensitive than albumin to acute changes in nutritional status. Normal serum concentrations of transferrin are 250 to 300 mg/dL.

Even more sensitive to changes in energy and protein intake is prealbumin (transthyretin), which has a small body pool (10 mg/kg) and a half-life of 2 to 3 days. Prealbumin transports both retinol and retinol-binding protein. Normal serum prealbumin concentrations are 15 to 40 mg/dL.

Retinol-binding protein has the shortest half-life, 12 hours; normal serum concentrations are 2.5 to 7.5 mg/dL. However, because serum concentrations of retinol-binding protein change rapidly in response to alterations in nutrient intake, monitoring it has limited use in clinical practice. The visceral proteins commonly used for nutritional assessment are summarized in Table 35-2.

Other proteins, such as fibronectin and somatomedin-C (insulin-like growth factor-1), are also used as markers of nutritional status. Fibronectin is a glycoprotein found in blood, lymph, and many cell surfaces. Somatomedin-C is important in regulating growth. Both fibronectin and somatomedin-C have half-lives of less than 1 day and respond to fasting and refeeding. Urinary measurement of 3-methylhistidine, a by-product of muscle metabolism that is excreted unchanged, has been used to estimate skeletal muscle mass. Although these markers have potential use in nutritional assessment, they are used primarily as research tools and are not readily available for routine clinical use.[25]

The interpretation of serum protein concentrations in hospitalized patients may be difficult because other factors more important than hepatic synthesis rate can alter serum concentrations. These factors may include renal, hepatic, or cardiac dysfunction, hydration status, and metabolic stress. Visceral proteins, as with any nutritional assessment parameter, must be used in conjunction with other parameters and comprehensive consideration of the patient’s clinical status. Practitioners should evaluate markers of inflammation and stress, such as C-reactive protein, in conjunction with visceral protein markers periodically to ensure that an accurate assessment is made.

Nutritional assessment based on determinations of body composition using anthropometric and biochemical parameters has many limitations. Newer techniques (e.g., bioelectrical impedance, dual-energy X-ray absorptiometry, isotope dilution, neutron activation) are increasingly being used to determine body composition. Other parameters such as hand grip and forearm dynamometry may be used to assess skeletal muscle function, which relates changes in body composition to body function.[1,9,25]

Another nutritional assessment method, subjective global assessment (SGA), combines objective parameters and physiologic function.[29] This easy-to-use tool for diagnosing malnutrition is based on a history of weight change, dietary intake, presence of significant GI symptoms, functional capacity, and physical examination to assess edema and the loss of subcutaneous fat and muscle. Using the SGA system, patients are rated as well nourished, moderately malnourished, or severely malnourished.

Classification of Malnutrition

Malnutrition is categorized through a variety of descriptive terms, each with varying characteristics. Three classic categories include marasmus, kwashiorkor, and mixed protein-calorie malnutrition. A chronic deprivation of energy (calories), or partial starvation, leads to marasmus, which means a "dying away state." For patients with marasmus, physical examination reveals severe cachexia with loss of both fat and muscle mass; however, visceral protein production is preserved, and serum levels may remain at or near the normal range. Patients with chronic wasting diseases such as cancer or anorexia are likely to present with marasmus malnutrition.

Classic kwashiorkor malnutrition results from diets devoid of adequate protein, but with adequate caloric intake. Kwashiorkor-like malnutrition in hospitalized patients often refers to patients who are extremely catabolic from their medical complication (e.g., sepsis) or injury (e.g., trauma, thermal injury). Carbohydrate metabolism involves endogenous production of insulin, which in turn prevents lipolysis and promotes the movement of amino acids into muscle. To meet increased protein demands, protein can be mobilized from internal organs and circulating visceral proteins. Consequently, an individual with kwashiorkor-like malnutrition may have adequate fat and muscle mass, but may demonstrate depleted serum proteins.

Hospitalized patients commonly exhibit components of both marasmus and kwashiorkor-like malnutrition and are classified as having mixed protein-calorie malnutrition. This mixed condition occurs when an acute injury or stress compounds chronic starvation or semistarvation, resulting in wasting of fat and muscle mass, as well as depletion of serum proteins.

Estimation of Energy Expenditure

Estimating energy expenditure constitutes an important aspect of patient evaluation. The most common approach used to determine energy requirements is based on body weight in kilograms. Energy requirements are standardized and are determined by the metabolic condition of the patient.

Many predictive equations for estimating expenditure have been described in the literature.[30,31] The traditional method of assessing energy expenditure is the basal energy expenditure (BEE): the amount of energy (kilocalories) needed to support basic metabolic functions in a state of complete rest, shortly after awakening, and after a 12-hour fast. BEE is most commonly calculated using the Harris–Benedict equations (see Table 35-3). Alternatively, BEE can be estimated at 20 to 25 kcal/kg/day.

Basal metabolic rate (BMR) is the energy expended in the postabsorptive state, approximately 2 hours after a meal. BMR is approximately 10% greater than BEE. Calculations of BEE or BMR do not include additional energy required as a result of stress or activity. The Harris–Benedict equations can be modified to include stress and physical activity factors, or these variables are estimated at 20 to 35 kcal/kg/day for moderate-to-severe stress (Table 35-3).

Indirect calorimetry determines energy expenditure using a machine known as a metabolic cart that measures the patient's breathing or respiratory gas exchange. The cart measures oxygen consumption and carbon dioxide production when standard testing conditions are maintained. The amount of oxygen consumed and carbon dioxide produced for carbohydrate, fat, and protein is constant and known. Energy expenditure, including that caused by stress, is measured for a defined time, and the information is then subjected to a series of equations to extrapolate the estimated 24-hour energy expenditure.[17,25] This is the measured energy expenditure (MEE). Because the measurement is usually conducted while the patient is at rest, activity is not included in MEE.

Table 35-3

Estimation of Energy Expenditure

Basal Energy Expenditure (BEE)
Harris–Benedict equations
BEE_{men} (kcal/day) = 66.47 + 13.75 W + 5.0 H – 6.76 A
BEE_{women} (kcal/day) = 655.10 + 9.56 W + 1.85 H – 4.68 A
Or
20–25 kcal/kg/day

Energy Requirements	
Hospitalized patient, mild stress	20–25 kcal/kg/day
Moderate stress, malnourished	25–30 kcal/kg/day
Severe stress, critically ill	30–35 kcal/kg/day

A, age in years; BEE, basal energy expenditure; H, height in cm; kcal, kilocalories; W, weight in kg.

Indirect calorimetry is available to many clinicians and is considered the gold standard for energy expenditure determination. Its usefulness is particularly valuable in the energy assessment of critically ill or obese patients. In 2016, the Society of Critical Care Medicine (SCCM) and American Society for Parenteral and Enteral Nutrition (ASPEN) published guidelines for the provision and assessment of nutritional support therapy for the adult critically ill patient.[32] Based on expert consensus, the guidelines suggest that determination of nutritional risk be performed on all ICU patients for whom volitional intake is anticipated to be insufficient. High-risk patients would likely benefit from early enteral nutritional therapy. Additionally, the guidelines suggest that the nutritional assessment should include evaluation of comorbid conditions, function of the gastrointestinal tract, and risk of aspiration. Traditional nutrition indicators or surrogate markers should likely not be used to assess nutritional status in critically ill patients because they have not been validated in the critically ill patient population.

Estimation of Protein Goals

Estimation of protein needs is necessary in nutritional assessment. Protein needs are calculated based on body weight, degree of stress, and disease state. The initial estimation is often made with a degree of subjectivity and clinical judgment, with adjustments made based on patient response. The US-recommended dietary allowance is 0.8 g of protein/kg/day. Well-nourished, hospitalized patients with minimal stress need 1 to 1.2 g of protein/kg/day to maintain lean body mass. The requirement for protein intake may be as high as 2 g/kg/day for a patient in a hypermetabolic, hypercatabolic state secondary to trauma or burns. In addition, protein provision may need to be adjusted and reduced in patients with renal or hepatic dysfunction as a result of altered metabolism. Guidelines for protein needs are summarized in Table 35-4.

Micronutrients

Micronutrients are the electrolytes, vitamins, and trace minerals needed for metabolism. A complete assessment will include identification of risks for deficiencies or toxicities with micronutrients based on the patient’s specific nutritional status and concurrent disease processes. These nutrients are available enterally and parenterally from various manufacturers as either single entities or in combinations. It is important to be aware of the specific products available in each institution to avoid providing inadequate or excessive amounts of various micronutrients.

Table 35-4

Estimation of Protein Requirements

US-recommended dietary allowance	0.8 g/kg/day
Hospitalized patient, minor stress	1–1.2 g/kg/day
Moderate stress	1.2–1.5 g/kg/day
Severe stress	1.5–2 g/kg/day

PATIENT ASSESSMENT: WOMAN WITH CROHN'S DISEASE

CASE 35-1

QUESTION 1: S.P., a 34-year-old cachectic woman, is admitted to the hospital with abdominal pain, nausea, vomiting, and diarrhea. She has a history of moderate Crohn's disease diagnosed 4 years ago. She has had extensive treatment with medical therapy, but has not required surgical intervention since her diagnosis. She has experienced extraintestinal symptoms including skin lesions and joint pain. She presents to the hospital with increasing weight loss in the past 3 months, accompanied by regurgitation, vomiting, and poor appetite. Approximately 6 months ago, S.P. weighed 120 lb. Her weight on admission is 92 lb; height is 60 inches. Past medical history is also significant for peptic ulcer disease and occasional bouts of depression. Physical examination reveals a thin woman with wasting of subcutaneous fat in the temporal area and square shoulders. She reports noticing recent hair loss. Attempts at increasing her oral intake with enteral supplements have not been successful owing to self-reported retching.

Admission laboratory values are as follows:
Sodium, 135 mEq/L
Potassium, 4.0 mEq/L
Chloride, 100 mEq/L
Bicarbonate, 25 mEq/L
Blood urea nitrogen, 4 mg/dL
Creatinine, 0.6 mg/dL
Glucose, 87 mg/dL
Calcium, 8.2 mg/dL
Magnesium, 1.7 mg/dL
Phosphorus, 2.8 mg/dL
Total protein, 6.0 g/dL
Albumin, 3.5 g/dL
Prealbumin, 14 mg/dL

Her white blood cell count is 12,600/µL. Based on history and physical findings, S.P.'s working diagnosis includes Crohn's disease exacerbation with cutaneous, joint, and GI involvement. What is her current nutritional status?

To develop an accurate nutritional assessment of any patient, it is important to elicit a thorough history and conduct an appropriate physical examination. Although history and physical examination are of paramount importance, laboratory studies are also integral components to the assessment of S.P.'s nutritional status. S.P.'s nutrition history indicates that she is unable to eat because of vomiting, and the Crohn's diagnosis raises the question of nutrient malabsorption. Most striking about S.P.'s history is her weight loss of 28 lb in 6 months. She is now 76% of

---

her usual weight (Eq. 35-2). Another way of analyzing this is that she has lost 25% of her original weight, which is characterized as severe weight loss. The physical findings of cachectic appearance, temporal wasting, and loss of subcutaneous fat and muscle in her shoulders are significant. No anthropometric measurements are available. S.P.'s visceral proteins are also in low–normal ranges, indicating both short-term (prealbumin) and long-term (albumin) malnutrition. Consideration of these factors leads one to conclude that S.P. is severely malnourished. This assessment can be further validated by using other tools such as the SGA.[29]

Because nutritional assessment can often be difficult, a clinician may choose to use the SGA to appropriately categorize their patients. Application of the SGA technique classifies patients into three areas: class A (the well-nourished patient), with less than 5% weight loss or more than 5% total weight loss but recent gains and improvements in appetite; class B (moderately malnourished), identified by those patients with 5% to 10% weight loss without recent stabilization or gain, poor dietary intake, and mild loss of subcutaneous tissue; and class C (severely malnourished), with an ongoing weight loss of more than 10% with severe subcutaneous tissue loss and muscle wasting, often with edema. The utility of the SGA is its simplicity for implementation and strong correlation with other subjective and objective measures of nutrition.

Clinicians place patients into one of the three categories on the basis of their subjective rating of two broad factors: history and physical examination. There are four elements to the history: (a) weight loss in the 6 months before the examination, expressed as a proportionate loss from previous weight, (b) dietary intake in relation to the patient's usual pattern, (c) presence of significant GI symptoms, and (d) functional capacity or energy of the patient, ranging from full capacity to bedridden. Applying these four elements to S.P., one first finds that S.P. is reporting a 25% weight loss during the past 6 months. It is also important to recognize the pattern of weight loss. Querying a patient regarding recent weight loss (in conjunction with the weight change in 6 months), often in the past 2 weeks, can help establish a pattern of chronic weight loss. In S.P.'s case, she reports increasing weight loss in the past 3 months, which confirms a progression. It is also recommended that clinicians explore weight history by asking for the patient's maximal weight at specific times, such as 1 year ago, 6 months ago, 1 month ago, and at the present time. Confirmation of weight history can be conducted by having the patient to discuss about his/her change in clothing size or how his/her clothes fit.

With respect to the second element regarding dietary intake, S.P. says she has a poor appetite, and attempts to consume supplements have been unsuccessful. Using the SGA, patients are classified as having either normal or abnormal intake in the weeks to months before the examination. In this case, S.P. is clearly experiencing abnormal intake; however, one can also ask S.P. certain questions such as "How has the amount of food you have consumed over the past several weeks to months changed?" or "Are there certain kinds of foods that you no longer can eat?" and "Give me an example of a typical meal" to establish eating patterns. It is also important to determine why a patient is eating less—intentional reduction or unintentional reduction. S.P. is not communicating any intention of wanting to lose weight, and her change in consumption is related to her chronic pathology.

In terms of the third element of the history, significant GI symptoms are those that have persisted on virtually a daily basis for a period longer than 2 weeks. Given the presentation of S.P. to the hospital with her history of 3 months of vomiting, it is highly likely that she satisfies the definition for possessing significant GI symptoms. However, a clinician can always clarify this by asking S.P. more specific questions.

The final element of S.P.'s history, functional capacity, is one that should be explored further; yet, it is not likely to have an impact on the final nutritional assessment given the prior objective findings of the patient. Patients who cannot eat will often complain of weakness and fatigue—many times to the point of which they are bedridden. Observation of the activity levels of patients, their overall mood, skeletal muscle function, and their respiratory movements can all provide clues to the clinician regarding functional impairment. Given the joint pain and squared-off appearance of her shoulders from the combination of muscle and subcutaneous tissue loss, functional capacity of S.P. is likely to be diminished.

Having completed the history component of the SGA, the clinician moves to the second component of the SGA, or the physical. This section of the SGA essentially asks the clinician to look for physical signs of malnutrition such as loss of subcutaneous fat in the triceps and chest region, muscle wasting in areas like the quadriceps and deltoids, presence of ankle or sacral edema, and finally any presence of ascites. For each of the traits, the clinician should consider the severity, if anything present. In the case of S.P., there is definite muscle wasting. Given the history and physical components of the SGA, S.P. would be classified as severely malnourished (class C) as there are obvious signs of malnutrition such as subcutaneous tissue loss and muscle wasting in the presence of a clear and convincing pattern of ongoing weight loss greater than 10%.

CASE 35-1, QUESTION 2: Is S.P. a candidate for specialized nutritional support therapy?

The fundamental goal of specialized nutritional support therapy is to meet the energy requirements of metabolic processes, to support the hypermetabolism associated with critical illness, and to minimize protein catabolism. Crohn's disease is a form of inflammatory bowel disease that is associated with potentially great nutritional insult. Nutritional abnormalities can arise in Crohn's disease patients from malabsorption, decreased food intake, medications, and intestinal losses. Disease location along the GI tract, symptomatology, and dietary restrictions all contribute to the development of protein energy malnutrition with specific nutritional deficiencies. S.P. is admitted to the hospital for tests to evaluate her Crohn's disease, weight loss, and associated symptoms. The subjective and objective evidence points to a nonfunctioning GI tract. If the diagnosis of advanced Crohn's exacerbation is accurate, S.P. may require parenteral nutritional therapy until enteral therapy can be established (see Chapter 38, Adult Parenteral Nutrition). In addition, previous attempts at enteral nutrition were unsuccessful with continued increased retching and vomiting, indicating decreased GI motility. With her malnourished state, continued inadequate nutrition in the hospital will result in further deterioration of her nutritional status. Specialized nutritional support intervention should be implemented.

Goals of Therapy

CASE 35-1, QUESTION 3: Calculate calorie and protein goals for S.P.

Nutritional support begins with an estimation of the patient's caloric requirements.[30,31] Accurate determination of caloric needs is essential to obtain the full benefits of nutritional therapy and aids in preventing the problems associated with underfeeding as well as overfeeding. The Harris–Benedict equation is one of the most commonly used methods for estimating caloric needs or BEE; however, there is still controversy regarding the best method to accurately estimate the caloric needs of a patient. The Harris–Benedict equation may overestimate or underestimate

---

resting energy expenditure in certain critically ill patients, particularly when clinical conditions are changing and when body weight fluctuates because of changes in fluid status. The most common approach is based on body weight in kilograms. The energy requirements are standardized and are determined by the metabolic condition of the patient. S.P.'s initial calorie goals are to meet her current energy expenditure needed for basal metabolism and activity of ambulating. S.P. would fall into the category of "moderate stress, malnourished" requiring 25 to 30 kcal/kg/day. For this calculation, S.P.'s actual weight of 92 lb (41.8 kg) should be used because her metabolism and current energy expenditure reflect this decrease in body mass. Using usual weight or IBW in patients who have severe weight loss may result in overfeeding. For S.P., the caloric goal should be from 1,045 to 1,255 kcal/day.

Protein is the building block of life. Once hepatic glycogen stores are depleted, muscle protein is degraded to provide three-carbon backbones for hepatic gluconeogenesis. Initially, protein catabolism is resistant to the administration of exogenous amino acids, and it can sometimes take weeks until a patient is found to be in a state of positive nitrogen balance. In addition to protein catabolism, exogenous protein is required for wound healing and to replace protein lost in wounds and fistulae. Protein goals are estimated based on weight, degree of stress, and disease state. The goal is to minimize the loss of lean body mass, and as a general rule this requires anywhere from 1.0 to 1.5 g/kg/day of protein depending on the degree of illness and injury. Because S.P. has not had surgery and her stress is minimal, her protein goal should be based on the desire to maintain her current protein status. Using the guidelines provided in Table 35-4, S.P.'s protein dose is 1.2 to 1.5 g/kg/day, or 50 to 63 g/day. As with energy expenditure, calculations of protein needs are only estimates; the patient's clinical course should be monitored, and the protein dose should be adjusted accordingly. If S.P. requires surgery, her energy or calorie goals should be reassessed to include an additional stress factor.

Micronutrients

CASE 35-1, QUESTION 4: What vitamin and mineral deficiencies would you expect to find in S.P.? What options are available to the clinician to address them?

The therapeutic effects of specialized nutritional support accrue through the combined provision of macronutrients and micronutrients. These elements support vital cellular and organ functions, immunity, tissue repair, protein synthesis, and capacity of skeletal, cardiac, and respiratory muscles. As with any medical therapy, a nutritional support regimen should be adjusted based on the requirements, response, and tolerance of the patient. Patients who have inflammatory bowel disease are particularly at risk for developing altered levels of vitamins and other micronutrients. The etiology of these micronutrient losses is multifactorial and encompasses decreased oral intake, increased losses secondary to diarrhea, and malabsorption. In particular, deficiencies in vitamin D, folate, vitamin B_{12}, calcium, magnesium, and zinc are common to this patient population.

Given the prevalence of these deficiencies, S.P. should be prescribed a daily multivitamin and mineral supplement. If it is determined that S.P. has significant fat malabsorption, a water-miscible fat-soluble vitamin formulation can be considered. There is an increased incidence of osteoporosis in patients with Crohn's disease (with or without corticosteroid use), and therefore, S.P. should be assessed to ensure that her calcium and vitamin D intake is normal. Recommended daily oral calcium requirements are from 800 to 1,500 mg/day, but increase from 1,500 to 2,000 mg/day when replacement is needed for a deficiency. S.P. should be consuming a daily amount of 400 international units of vitamin D orally; however, if serum 25-hydroxyvitamin D levels are subtherapeutic, greater amounts will be required and also doses based on the specific disease progression and functionality of S.P.'s GI tract.

Medications such as methotrexate (a folate antagonist) and sulfasalazine (which blocks folate absorption) can be used to treat inflammatory bowel disease and, therefore, increase folate requirements for patients. Daily folate supplementation at a dose of 1 mg orally can be beneficial to S.P. if she is prescribed either of these medications.

Patients with surgical resection of the stomach or terminal ileum are at risk of developing vitamin B_{12} deficiency given the locations of intrinsic factor production and site of absorption, respectively. Given that S.P. has had no surgical intervention to date, it is wise to monitor her vitamin B_{12} status and look for signs of deficiency (i.e., megaloblastic anemia) before instituting aggressive supplementation.

Magnesium deficiency can be a concern in patients with increased intestinal losses, as is the case with many individuals who have inflammatory bowel disease. When considering enteral magnesium supplementation, the change in pH along the GI tract, GI transit time, and fat content of a meal can all affect magnesium absorption. Large doses of enteral magnesium can result in diarrhea; therefore, administering smaller doses throughout the day can lead to improved tolerance and therapeutic efficacy. Choosing a magnesium supplement that can deliver 150 mg of elemental magnesium and dosing it 4 times a day is the recommended oral replacement regimen for patients.

Inflammatory bowel disease patients can experience excessive stool losses resulting in a zinc deficiency. S.P. should receive an oral zinc supplement that delivers 50 mg of elemental zinc daily.

Maintenance Fluids

CASE 35-1, QUESTION 5: Determine the daily fluid requirements for S.P. while she receives specialized nutritional support.

When determining the fluid needs of a patient, the clinician should consider the following steps: (a) correction of fluid imbalances, (b) maintenance fluid requirements, and (c) replacement of ongoing fluid losses.

The extended periods of diarrhea, vomiting, or both that occur with inflammatory bowel disease may lead to dehydration. Dehydration results in a loss of body weight, decreased urine output, dry mouth, and progressive thirst. Hypotension, tachycardia, and poor skin turgor are all clinical signs of dehydration. Apathy, stupor, coma, and death will follow if fluid replacement is not undertaken. Fluid deficits should be estimated from the clinical appearance of the patient, recent weight loss, and serum sodium and blood urea nitrogen concentrations, and replaced by giving half the estimated deficit intravenously over the course of 8 hours. After 8 hours, a new assessment of fluid status should be made, and half of the new estimated deficit should be replaced during the next 8 hours. This process should be repeated until normal hydration is achieved (see Chapter 10, Fluid and Electrolyte Disorders).

Maintenance fluid is that volume of daily fluid intake that replaces the insensible losses and at the same time allows excretion of the daily production of excess solute load in a volume of urine that is of an osmolarity similar to plasma. Maintenance fluid needs can be estimated using several methods. The simplest method uses 30 to 35 mL/kg/day as the basis. Another method is to provide 1,500 mL for the first 20 kg of body weight plus an additional 20 mL/kg for actual weight beyond the initial 20 kg.

Both methods provide estimates of fluid needs for basic maintenance. S.P.’s fluid needs are estimated as follows:

$$\begin{aligned}\text{mL/day} &= 1{,}500\ \text{mL} + ([20\ \text{mL/kg}][41.8\ \text{kg} - 20\ \text{kg}]) \\ &= 1{,}500\ \text{mL} + (20\ \text{mL/kg})(21.8\ \text{kg}) \\ &= 1{,}500\ \text{mL} + 436\ \text{mL} \\ &= 1{,}936\ \text{mL}\end{aligned} \tag{Eq. 35-3}$$

If S.P. experiences vomiting, nasogastric tube output, diarrhea, or other significant fluid losses, additional fluid must be provided. Some losses are measurable and can be directly replaced milliliter for milliliter on a regular basis. Others, however, are not measurable and can only be estimated. The electrolyte composition of the lost fluid is an important consideration for the clinician and dictates the ultimate choice of the replacement fluid.

Evaluating Specialized Nutritional Support Effectiveness

CASE 35-1, QUESTION 6: What parameters should be examined to determine the effectiveness of S.P.’s nutritional support regimen?

Implementing a successful nutritional support regimen begins with proper nutritional assessment of the patient. Nutritional goals that identify macronutrient, micronutrient, and fluid requirements are then established. Follow-up support and monitoring of the patient once nutritional support has been instituted is important to maintain the integrity and efficacy of the therapy.

To minimize the risk of refeeding syndrome in S.P. (a metabolic and electrolyte disturbance that occurs as a result of supplying nutrition to patients who are severely malnourished), all electrolyte abnormalities must be corrected before any nutrition is initiated. Because S.P.'s electrolytes are within normal ranges, no adjustments are necessary. Nutrition should then be implemented slowly, and vitamins administered routinely. Electrolytes, including phosphorus, potassium, magnesium, and glucose, should be monitored at least daily during the first week. Although electrolyte and mineral abnormalities may not be avoided, careful recognition of and close monitoring for refeeding syndrome will prevent serious complications.[33,34]

Although it can sometimes be difficult to obtain a reliable weight for a patient, weight can be an important parameter to help assess not only fluid balance but also the long-term appropriateness of caloric intake. Most patients should gain or lose no more than 1 kg/week when receiving nutritional support (assuming normal fluid status). However, clinicians must be aware of the impact that fluids have on the weight of a patient. Large intake or loss of fluids can influence weight measurements and mask the trends of body mass. Having S.P. record of daily weights, in addition to fluid intake and output, and monitoring trends can serve as one, but not the only, key in determining the effectiveness of her regimen.

Nitrogen balance is another parameter that can help determine the degree of catabolism and protein requirements in a patient. Nitrogen balance is the difference between nitrogen intake and nitrogen excretion. It is estimated by the nitrogen intake along with collecting a 24-hour urine urea nitrogen sample from the patient. Positive nitrogen balance is a reasonable goal during nutritional support therapy for recovery of a patient, but may also require increasing caloric loads on a periodic basis. If a nitrogen balance study is ordered for S.P., increasing protein intake should be considered if results indicate a negative nitrogen balance; however, a negative nitrogen balance may be unavoidable during high-stress states, regardless of the amount of nutrients provided.

Finally, prealbumin levels for S.P. should also be monitored once a week as a marker for short-term gross adequacy of calorie and protein intake. A lack of prealbumin increase is an indicator of poor patient outcomes. With adequate feeding, prealbumin can increase more than 4 mg/dL/week. It should be noted that in the case of S.P. who is suffering from Crohn's disease and may likely be receiving either oral or parenteral corticosteroids as treatment, administration of corticosteroids can falsely elevate prealbumin levels, making S.P. appear to be at a lower nutritional risk.

CASE 35-1, QUESTION 7: Members of the medical team are anxious to have S.P. gain weight and are concerned by her malnourished appearance. Therefore, there is a desire to increase the calories provided to S.P. What potential complications could result from overfeeding S.P.?

Overfeeding should be avoided in all patients because of a plethora of potential complications, especially those with respiratory concerns.[35] Although restoration and maintenance of body cell mass is the goal of nutritional support therapy, a gradual and conservative approach yields fewer metabolic abnormalities. Supplying an abundance of calories to a patient in need of nutritional support increases the metabolic rate, which in turn places greater demands for cardiopulmonary effort and oxygenation. Overfeeding with carbohydrates is particularly detrimental because of the amount of carbon dioxide produced relative to the amount of oxygen consumed. This results in carbon dioxide retention that may lead to acid–base disturbances. Hyperglycemia is also a common metabolic abnormality secondary to excessive carbohydrate administration that can lead to osmotic diuresis and immune dysfunction.

Obesity

Dhiren K. Patel and Kaelen C. Dunican

	CORE PRINCIPLES	CHAPTER CASES
1	Body mass index (BMI) should be measured at each patient encounter and patients should be assessed for overweight and obesity and the risk for related comorbid conditions.	**Case 36-1 (Questions 1, 3)**
2	An understanding of body composition is essential when evaluating the health status of a patient with regard to body fat.	**Case 36-1 (Question 1)**
3	The medication lists of patients with increased body weight should be evaluated for drugs associated with weight gain and alternative agents that are weight neutral or associated with weight loss should be considered.	**Case 36-1 (Question 1)**
4	Obesity is a chronic disease and therapeutic interventions must be long term.	**Case 36-1 (Questions 2, 7)**
5	An appropriate weight loss goal is 5% to 10% of baseline body weight in 6 months.	**Case 36-1 (Question 4)**
6	Management and treatment of overweight and obesity should include a combination of diet and increased physical activity along with behavioral modifications.	**Case 36-1 (Questions 4, 5)**
7	Medication to treat obesity should be considered for patients with a body mass index greater than 30 kg/m^2 without risk factors or greater than 27 kg/m^2 with an obesity-related risk factor such as hypertension, dyslipidemia, sleep apnea, cardiovascular disease, and type 2 diabetes	**Case 36-1 (Questions 6, 7, 9)**
8	Short-term weight loss drugs are unlikely to be clinically useful and should not be recommended.	**Case 36-1 (Question 6)**
9	Medication for chronic weight management includes orlistat, phentermine/topiramate, lorcaserin, naltrexone/bupropion, and liraglutide.	**Case 36-1 (Question 7)**
10	The use of dietary supplements for weight loss is not supported by clinical literature and should be avoided due to safety concerns and lack of regulation.	**Case 36-1 (Question 8)**
11	Bariatric surgery may be considered for patients with a BMI >40 or BMI >35 with obesity-related comorbid conditions.	**Case 36-1 (Question 10)**

⑫ Alteration of gastrointestinal tract and stomach size after bariatric surgery can alter drug pharmacokinetics and place patients at risk for adverse events associated with some medications.	**Case 36-1 (Question 10)**

Obesity is a chronic disease that is characterized by excess body fat accumulation which may impair health.[1,2] The prevalence of obesity has become an epidemic. More than two-thirds of the US adult population is overweight with more than one-third considered obese.[3] And more than one-third of the worldwide population is overweight.[4] It is recognized by the World Health Organization (WHO) and US Federal Government as a growing problem that is burdening our healthcare organizations and economy. Analyses estimate the total annual US economic costs associated with obesity are in excess of $215 billion.[5]

DEFINITIONS

Overweight and obesity are defined by body mass index (BMI), a measure of weight in relation to height. BMI is calculated as weight (in kg) divided by height (in meters) squared. Normal weight is defined as BMI of 18.5 to less than 25 kg/m^2; overweight is defined as BMI greater than or equal to 25 to less than 30 kg/m^2; and obesity is defined as BMI greater than or equal to 30 kg/m^2 (Table 36-1).[6,7] Obesity is further divided into class I (BMI ≥30–35 kg/m^2), class II (BMI ≥35–40 kg/m^2), and class III (BMI ≥40 kg/m^2). Class III obesity is also referred to as extreme or severe obesity and was formerly known as morbid obesity. Obesity is a chronic metabolic disorder that is determined by multiple biologic and environmental factors, an obesogenic lifestyle, and a genetic predisposition. The increase in the prevalence of obesity and negative health outcomes are major public health problems throughout the world.[1,8]

Body mass index (BMI) is widely accepted as the standard to classify weight. However, a major limitation of BMI is that it does not consider body composition. According to BMI, a person may be classified as “overweight” if their muscle mass is great enough to significantly contribute to total weight. On the other hand, a patient may be considered “normal weight” while having excess fat accumulation and decreased muscle mass. The use of BMI to assess body fat and risk of morbidity and mortality is particularly problematic in certain ethnic groups because BMI does not account for differences in distribution of body fat. For example, research suggests that in the Asian population, BMI underestimates body fat.[9]

Fat distribution in the abdominal region has been linked to many of the metabolic consequences of obesity.[10] Measurement of waist circumference (WC) is used to assess for increased abdominal fat accumulation and to determine health risk. Waist circumference measurements greater than 102 cm (40 inches) in men and 88 cm (35 inches) in women are associated with increased risk of metabolic diseases.[10] Increased WC has been shown to predict obesity-related diseases such as diabetes, hypertension, dyslipidemia, and cardiovascular disease.[10–12] The waist-to-hip ratio (WHtR) also provides an assessment of regional fat distribution. A waist-to-hip ratio >1 in men and >0.8 in women indicates high intra-abdominal fat. Some research suggests that WHtR is superior to both WC and BMI in determining obesity-related cardiometabolic risk. Independent of BMI classification, higher waist circumference is correlated with increased mortality.[13] Therefore, measurement of WC and the WHtR are useful in identifying individuals that are normal weight or overweight with health risk due to increased abdominal fat accumulation.

Table 36-1

BMI and Guidelines for Weight Classes

Weight Status	BMI[a]	Obesity Class
Underweight	<18.5	
Normal	≥18.5–25	
Overweight	≥25–30	
Obesity	≥30–35	I
	≥35–40	II
Extreme or severe obesity	≥40	III

[a] Metric conversion formula using kilograms and meters: BMI = Weight in kg/height in m^2. Nonmetric conversion formula using pounds and inches: BMI = weight in lb/height in $\text{inches}^2 \times 703$.

BMI, body mass index.

EPIDEMIOLOGY

Obesity is a major public health concern worldwide and is a leading cause of numerous medical conditions (e.g., cardiovascular disease, hypertension, dyslipidemia, diabetes, sleep apnea) and premature death[10,13] (Table 36-2). According to the WHO, there were approximately 1.9 billion overweight and 600 million obese adults globally in 2014.[1] In the United States, the prevalence of obesity has been examined as part of the National Health and Nutrition Examination Survey

(NHANES). The NHANES data from 2011 to 2012 showed that 68.5% of US adults were overweight or obese and 34.9% were obese and 6.4% were extremely obese.[3] Adult obesity usually results from a steady weight gain from the mid-20s to between ages 40 and 59, when the prevalence of obesity peaks.[3] Severe obesity is more common in women.[3] The most recent NHANES data report overweight, obesity, and extreme obesity were more prevalent among non-Hispanic black women.[3] Despite the striking increases in obesity prevalence in the 1980s and 1990s, current NHANES data suggest that the prevalence of obesity may be stabilizing, showing nonsignificant increases compared with the 2003 to 2004 NHANES data.[3]

Table 36-2

Obesity-Related Health Conditions

Cardiovascular	Dermatologic
Hypertension	Striae distensae (stretch marks)
Heart failure	Skin tags
Coronary artery disease	Acanthosis nigricans
Stroke	Intertrigo
Pulmonary	**Gastrointestinal**
Obstructive sleep apnea	Gallstones
Asthma	Gastroesophageal reflux disease (GERD)
Metabolic	**Psychological**
Dyslipidemias	Eating disorders
Diabetes mellitus	Depression
Hyperinsulinemia	Social stigma
Cancer	**Gynecologic and Obstetric Complications**
Esophageal	Gestational diabetes
Colon	Preeclampsia
Liver	Infertility
Prostate	**Musculoskeletal**

Obesity is also a significant problem among children and adolescents, with alarmingly high prevalence rates. Overweight and obesity in children and adolescents (age 2–19 years) are based on the Centers for Disease Control (CDC) growth charts; overweight is defined as BMI in the 85th to 95th percentile and obese is defined as BMI greater than the 95th percentile.[7] The WHO estimates that greater than 42 million children under age 5 are overweight.[1] NHANES data from 2011 to 2012 reported that 31.8% of children and adolescents (age 2–19 years) were either overweight or obese and 16.9% were obese.[3] Non-Hispanic white youth show lower prevalence of obesity as compared to non-Hispanic black and Hispanic youth. As with adults, the prevalence has stabilized, with no significant change compared with the 1999 to 2000 NHANES data.[3] However, because this prevalence rate has remained alarmingly high, childhood obesity must be addressed because of the health consequences the obese child takes on into adulthood. Childhood and adolescent obesity shows an increased risk for adult overweight and obesity.[14] Also, studies have shown that overweight and obesity in childhood and adolescence are correlated with an increased risk of adult diabetes, hypertension, ischemic heart disease and stroke physical morbidity, and premature mortality.[15]

ETIOLOGY AND PATHOPHYSIOLOGY

Simply stated, obesity results from an imbalance of energy intake and energy expenditure. Body fat accumulation will occur when an individual consumes more calories than are burned. However, the exact cause of obesity is difficult to identify and is likely a mixture of genetic, environmental, behavioral, and neurohormonal factors. Investigators have tried to understand the origin of this disease by studying the influences of society, culture, socioeconomic status, medical conditions, medications that stimulate appetite, parental weight, and hereditary traits on dietary habits and physical activity.[16] Each potential cause of obesity continues to be investigated as a possible target for treatment and prevention of this chronic disease.

There have been several association studies linking short sleep duration and metabolic changes such as obesity, insulin resistance, and diabetes.[17,18] One study showed that children aged 30 months and younger who lacked sleep were at risk of exhibiting obesity at 7 years.[19] Another trial in adults found that sleep duration was negatively correlated with BMI.[20] Alteration of the hypothalamic regulation of appetite and energy expenditure owing to sleep loss is one possible explanation. Normally, when a person has eaten an adequate amount of food, neurotransmitters or peptides in the brain signal the satiety centers in the hypothalamus and there is a reduced desire to eat. Sleep loss has also been shown to be associated with low leptin levels and high ghrelin levels; both factors contribute to signaling of energy deficit and hunger, which may contribute to overeating and obesity.[21]

Recently, research has begun to investigate the role of that gut microbiota in body composition. Data suggest that interventions that negatively impact the biodiversity of the gut microbiota such as Cesarean delivery (vs. vaginal delivery), maternal prepregnancy BMI, and early antibiotic use may increase the risk of obesity.[22] A large cohort trial found that the repeated use of broad-spectrum antibiotics during the first 2 years of life has been associated with early childhood obesity.[23]

Genetic Features

There is a clear link between genetics and obesity, both in childhood and adulthood, shown mostly through twin and adoption studies.[24–29] One study by Wardle et al.[26] demonstrated a heritability estimate of 77% for BMI and 76% for waist circumference. Genetic studies have identified genes that may be associated with weight.[24,30] There is also evidence that body fat distribution is controlled by genetic factors with waist-to-hip ratio showing heritability of up to 60%.[31]

HYPOTHALAMUS DYSREGULATION

The hypothalamus plays a key role in body weight regulation by controlling satiety (the feeling of fullness), hunger, and in turn food intake. Neurobiologic theories of eating disorders have focused on dysregulation of the hypothalamic–pituitary–adrenal, hypothalamic–pituitary–gonadal, and hypothalamic–pituitary–thyroid axes as well as dysregulation of neurotransmitters, neuropeptides, endogenous opioids, growth hormone, insulin, and leptin.[32] Alterations in hypothalamic functioning are associated with appetite changes, mood disorders, and neuroendocrine disturbances.[33] The hypothalamus is the major appetite and eating control center in the brain and is sensitive to a variety of facilitatory and inhibitory neurotransmitters and polypeptide neurohormones from the brain and gastrointestinal (GI) tract. The hypothalamus receives input from peripheral satiety sites (e.g., gastric and pancreatic peptides released secondary to food passing through the GI tract), from leptin that is produced by fat cells, and from the catecholamine neurotransmitter system in the brain.[33,34]

NEUROTRANSMITTER DYSREGULATION

Serotonin

Serotonin plays an important role in postprandial satiety, anxiety, sleep, mood, obsessive–compulsive, and impulse control disorders. Serotonin has an inhibitory effect on appetite and is responsible for satiety or the feeling of fullness after food intake.[35,36] Diminished serotonin activity can contribute to increased food intake and carbohydrate craving.[35] The reduction in serotonin activity may upregulate the appetite or satiety centers in the brain, thereby increasing the amount of food a person wants to eat. Agents that block postsynaptic serotonin activity (e.g., clozapine, mirtazapine, and atypical antipsychotics) can stimulate appetite and may cause weight gain.

Dopamine

Agents that increase dopamine activity (e.g., apomorphine, a dopamine agonist; levodopa, a metabolic precursor of dopamine; and amphetamine, a stimulator of release of dopamine from presynaptic stores) have been shown to have anorexic effects.[37] Dopamine agonists increase dopaminergic transmission and motor activity, which causes loss of appetite and hyperactivity. The central nervous system (CNS) effects of dopaminergic agents occur in the cerebral cortex, in the reticular activating system, and in the hypothalamic feeding center. The mesolimbic–mesocortical dopaminergic circuits are important for behavior reward and reinforcement, and are involved with "addictive" behaviors.[37] Dopamine-augmenting agents such as amphetamines were once used for the treatment

of exogenous obesity and produced tolerance, dependence, and withdrawal reactions. Conversely, dopamine receptor antagonists such as chlorpromazine and clozapine may cause dysphoria and are often associated with weight gain.

Norepinephrine

The hypothalamus is innervated by noradrenergic pathways; thus, norepinephrine is involved in the regulation of eating behavior, the hypothalamic control of thyrotropin-releasing hormone secretion, corticotropin-releasing hormone (CRH) release, and gonadotropin secretion.[37] D-Amphetamine, which inhibits the reuptake of norepinephrine, decreases hunger sensations and food intake. Abnormalities in leptin and β_3-adrenergic activity have been associated with obesity and diabetes.[38] The β_3-adrenoceptor is involved in a feedback loop with leptin to regulate energy balance, lipolysis in adipocytes, serum insulin levels, and food intake.[39] People with hereditary obesity or type 2 diabetes mellitus may have abnormalities in the β_3-adrenoceptor or in leptin activity, signaling, or receptors.[38] A genetic variant of the β_3-adrenoceptor in humans has been associated with severe obesity and type 2 diabetes. It is possible that some cases of obesity may be secondary to failure of the β_3-adrenoreceptor on brown adipocytes to respond appropriately to leptin-induced sympathetic activity. β_3-Adrenergic receptor agonists are being studied to induce thermogenic activity and promote weight loss when combined with a calorie-restricted diet.[39]

NEUROPEPTIDE AND LEPTIN DYSREGULATION

Leptin

Leptin is a protein synthesized by adipocytes, gastric chief cells, skeletal muscle, and other organs. It acts on receptors of the hypothalamus to act as an afferent satiety signal in the brain to regulate body fat mass.[33,40,41] Leptin reduces food intake, decreases serum glucose and insulin levels, increases metabolic rate, and reduces body fat mass and weight by reducing neuropeptide Y (NPY) activity (a potent feeding stimulant secreted by the hypothalamus and cells in the gut).[40,42] Leptin serum levels are highly correlated with BMI and body fat and its secretion has a circadian rhythm and an oscillatory pattern similar to other hormones.[38,41,43]

Leptin is supposed to signal the brain to reduce the desire to eat, but this does not occur in patients with obesity.[40] It has been postulated that some individuals with obesity may have partially resistant hypothalamic receptors or that there is a defect in the blood–brain barrier transport system for bringing leptin into the brain.[33,40,43,44] Cerebrospinal fluid leptin levels in some patients with obesity have been found to be much lower than expected compared with serum leptin levels, which suggests that the uptake of leptin into the brain may be defective.[33] Other studies suggest that obese individuals may have a dysregulation of leptin in response to overfeeding, with a lack of serum increase. Compared with lean individuals, this may indicate that the patients with obesity lack a protective mechanism of increase in serum leptin levels in response to increased caloric intake to prevent weight gain.[45] It has been demonstrated that elevated baseline serum leptin levels are associated with inability to maintain weight loss.[46] Another potential mechanism may be reduced leptin receptor protein expression found in skeletal muscle of patients with obesity that could lead to leptin resistance in the presence of elevated leptin serum levels.[47] Leptin and leptin-like products have been investigated for promotion of weight loss, but leptin resistance impedes its clinical utility.[40,48]

Neuropeptides and Neurohormones

Appetite is regulated in part via orexigenic neuropeptides which signal hunger and anorexigenic neuropeptides which signal satiety within the hypothalmus. Neuropeptide Y (NPY) and agouti-related peptide (AgRP) are found in the central nervous system and are potent stimulators of appetite.[49,50] POMC (pro-opiomelanocortin) is a precursor protein to α-melanocyte-stimulating hormone (α-MSH) and binds to melanocortin-3 receptors (MC3R) and melanocortin-4 receptors (MC4R) to suppress food intake.[34,49] Research on MC4R analogs is ongoing, but trials with selective MC3R agonist failed to suppress feeding.[34,49]

Several other neurohormonal signals and peptides play a role in appetite regulation. Ghrelin is a hormone that is released from the stomach before meals and acts to increase appetite via stimulation of NPY and AgRP. [49] There is a negative correlation between ghrelin levels and BMI where patients with obesity have increased ghrelin and levels remain elevated even after weight loss.[49] Peptide tyrosine tyrosine (peptide YY or PYY) and pancreatic polypeptide (PP) are pancreatic are chemically related to NPY but work as appetite suppressants.[49,50] Early studies of experimental PYY administration have found an intranasal formulation to be ineffective for weight reduction and poorly tolerated in obese patients.[51] A small dose escalation study of subcutaneous injections of two forms of PYY, PYY $_{1–36}$, and PYY$_{3–36}$, found some positive results on inducing lower subjective hunger and thirst ratings and higher satiety ratings with PPY$_{3–36}$ administration.[52] Amylin is a pancreatic hormone that is released in response to eating and functions as an anorectic hormone.[49] Administration of amylin has been shown to result in reduced food intake and weight loss.[53] Glucagon-like peptide-1 (GLP-1) is secreted from the gut in response to food intake and works to reduce food intake, suppress glucagon secretion, and delay gastric emptying.[49] Cholecystokinin (CCK) is a hormone that is released from the small intestines in response to food intake and works to suppress further food intake.[49]

Environmental Influences and Behavioral Factors

Despite the known genetic influences predisposing certain individuals to obesity, environmental influences play a role by providing exposure to a lifestyle promoting energy imbalance and may influence epigenetic factors. Modern society provides an overabundance of inexpensive, readily accessible calorie-dense food. Decreased energy expenditure due to a sedentary lifestyle has become common, further exacerbating an obesogenic lifestyle. A review of twin and adoption studies by Silventoinen et al.[25] clearly demonstrated that environmental factors affect BMI variation in childhood, but the effect of common environment disappears in adolescence. These results portray a stronger influence of genetics in the incidence of obesity in adulthood.

Medical Conditions and Medications

Although less common, certain medical conditions may cause overweight and obesity.[6] Genetic syndromes may be the primary cause of obesity such as Prader–Willi, Bardet–Biedl, Cohen, Alström, and Froehlich syndromes. Other primary causes of obesity include monogenic disorders such as melanocortin-4 receptor mutation, leptin deficiency, and POMC deficiency. Secondary causes of obesity include neurologic issues such as brain injury, brain tumors, and hypothalamic injury. Endocrine disorders may also be a secondary cause of overweight and obesity such as polycystic ovarian syndrome, Cushing syndrome, and growth hormone deficiency. Hypothyroidism is often cited as a secondary cause of obesity because elevated TSH is correlated with obesity.[54] But the relationship between hypothyroidism and obesity is complex; because leptin and melanocortin influence the release of TSH, causality has yet to be established.[54–56] Psychological causes of obesity include eating disorders and depression when associated with overeating or binging. Several medications are associated with weight gain. These include antipsychotics, steroids, insulin, sulfonylureas, thiazolidinediones, some antidepressants, and some anticonvulsants.[57] When treating overweight and obesity, if medications associated with weight gain are identified, substitution with possible alternatives should be attempted. Table 36-3 provides a list of medications that may cause weight gain along with potential alternatives.

Table 36-3

Common Drugs and Their Effect on Weight

	Associated with Weight Loss	Associated with Minimal Weight Gain or Weight Neutral	Associated with Weight Gain
Antidepressants	Bupropion	Fluoxetine, imipramine	TCAs, MAOIs, paroxetine, fluvoxamine, venlafaxine, duloxetine, mirtazapine
Antipsychotics		Aripiprazole, quetiapine, ziprasidone	Clozapine, olanzapine, risperidone
Neurologic	Topiramate, zonisamide, felbamate	Lamotrigine	Valproic acid, gabapentin, pregabalin, carbamazepine, vigabatrin, lithium
Glucose-lowering	GLP-1 agonists, metformin, pramlintide, SGLT-2 inhibitors	DPP-4 inhibitors, α-glucosidase inhibitors	Insulin, sulfonylureas (especially glyburide), meglitinides, thiazolidinediones
Antihypertensives		ACEIs, ARBs, CCBs, doxazosin	β-adrenergic blockers, (especially propranolol), α-adrenergic blockers (prazosin, terazosin)
Contraceptives		Barrier methods, Oral contraceptives	Injectables (especially medroxyprogesterone)
Antihistamines		Second generation	First generation
Anti-inflammatory		NSAIDs, DMARDs	Corticosteroids

ACEI, angiotensin converting enzyme inhibitor; ARB, angiotensin receptor blocker; CCB, calcium channel blocker; DMARD, disease-modifying antirheumatic drug; DPP-4, dipeptidyl peptidase-4; GLP-1, glucagon-like peptide-1; MAOI, monoamine oxidase inhibitor; NSAID, nonsteroidal anti-inflammatory drug; SGLT-2, sodium-glucose-linked transporter-2; TCA, tricyclic antidepressant.

CLINICAL FEATURES

CASE 36-1

QUESTION 1: S.B. is a 48-year-old woman with a past medical history of hypertension, sleep apnea, osteoarthritis, and depression. She states that she has been overweight since she was a toddler. She reports having tried multiple diets during the past 30 years, but has had little success with weight loss and always regains any weight she manages to lose. Her height is 168 cm, current weight is 91 kg, and WC is 96 cm. She presents to her primary physician for a routine physical examination. She complains of dissatisfaction with her weight. She reports having tried multiple diets during the past 20 years, but has had little success with weight loss and always regains any weight she manages to lose. S.B. expresses a desire to attempt medication therapy for weight loss. Her current medications include hydrochlorothiazide, metoprolol, naproxen, and paroxetine. Her blood pressure is currently 162/98 mm Hg and she is complaining of daytime fatigue due to sleep apnea. How is obesity defined and assessed in a patient like S.B.?

Initial Assessment

Current guidelines suggest that weight status should be assessed in all patients.[6,7] Initial assessment involves a physical exam and patient interview to classify the presence of overweight or obesity and any obesity-related comorbidities. The preferred method to classify overweight or obesity is to measure the BMI. Measurement of WC will also aid in determining risk of obesity comorbidities. However, measurement of waist circumference in patients with BMI greater than 35 kg/m^2 is not necessary because it will likely be elevated and will add no additional risk information.[7,12] BMI, WC, and obesity-related comorbidities are used to determine the need to initiate treatment. S.B.'s BMI is 32.2 ($91\ kg/[1.68\ m]^2$), which is in obesity class I. Her waist circumference is greater than 88 cm, indicating abdominal obesity that puts her at additional risk for increased morbidity and mortality. S.B. also has hypertension, sleep apnea, and osteoarthritis, which are likely related to obesity and will need to be considered in her overall care plan.

During the patient interview, information should be obtained regarding the patient's eating habits and physical activity. It is important to establish baseline data so that response to changes in diet and exercise is noted throughout treatment. Successful weight loss involves a change in energy balance through reduced caloric intake or increased energy expenditure. In S.B.'s case, it will be beneficial to evaluate her current diet and physical activities to determine the most appropriate lifestyle recommendations. It is also important to evaluate a patient's "weight loss readiness" or self-motivation before initiation of therapy. A patient's motivation to lose weight is a significant predictor of success or failure in the weight management program. S.B.'s desire and willingness to make significant lifestyle changes in order to achieve this should be evaluated.

Patients should also be screened for medical conditions or medications that can increase the risk for obesity, and these underlying factors should be corrected before recommending treatment. S.B.'s past medical history does not indicate any overt medical causes of obesity, but it would be appropriate to rule out whether she is overeating due to her depression and to check thyroid function to rule out hypothyroidism. Even though causality between obesity and thyroid dysfunction has yet to be firmly established, hypothyroidism is a common condition in women and may be associated with weight gain or inability to lose weight. S.B. is currently taking paroxetine for depression which has been associated with weight gain.[6,58] S.B.'s prescriber may want to consider switching to fluoxetine which is the SSRI that is associated with the least amount of weight gain or bupropion which is associated with weight loss (Table 36-3).[6,57,58]

Course and Prognosis

CASE 36-1, QUESTION 2: S.B. states that she has struggled with her weight her whole life. She has progressively gained approximately 2 kg/year since her 20s.What is the typical course and prognosis of obesity?

Obesity is a chronic disease that often begins in childhood or adolescence and can be characterized by a slow and steady increase in body weight during adult life. Most patients with obesity battle with weight loss and regain throughout their entire lives. The biologic response to weight loss favors regain with increased ghrelin and reductions in GLP-1, CCK, leptin, and PYY resulting in increased hunger.[6,59] Maintaining weight loss is key to long-term management of obesity. S.B. should be assured that her struggle is common and that she will need to commit to long-term lifestyle changes to manage her obesity.

Medical Complications

CASE 36-1, QUESTION 3: S.B. understands that she already has hypertension, sleep apnea, and osteoarthritis, which are comorbidities that are related to her obesity and increase her risk of morbidity and mortality. She is also at risk for experiencing additional obesity-associated medical comorbidities if she does not lose or continues to gain weight. What are the other common medical conditions associated with obesity? What impact will weight loss have on comorbid conditions?

Obesity is associated with an increased risk of morbidity and mortality. Some obesity-associated diseases that are generally not life-threatening include dermatologic complications, osteoarthritis, reproductive complications, gallstones and their complications, and stress incontinence. Other obesity-related conditions have a tremendous impact on physiologic functioning and medical illnesses. Obesity is linked to many significant health conditions such as type 2 diabetes mellitus, respiratory conditions, gallbladder disease, cancers, osteoarthritis, cardiac disease (hypertension, stroke, congestive heart failure, and coronary heart disease), dyslipidemia and dermatologic problems (intertrigo and stretching of skin), and gynecologic and obstetric complications (Table 36-2).[60,61] Weight loss helps to control diseases associated with obesity and may even help prevent development of these diseases.

Health benefits have been shown with modest sustained weight loss. Weight loss of 2% to 5% is associated with reducing hemoglobin A1C by 0.2% to 0.3% in patients with type 2 with overweight or obesity and weight loss of 5% to 10% is associated with up to 1% reduction in A1C.[7] Five percent weight loss is associated with reducing systolic blood pressure by 3 mm Hg and diastolic blood pressure by 2 mm Hg. Weight loss of 5 to 8 kg has been shown to reduce low-density lipoprotein cholesterol (LDL-C) by approximately 5 mg/dL and increase high-density lipoprotein cholesterol (HDL) by 2 to 3 mg/dL and triglycerides are lowered by 15 mg/dL with just 3 kg weight loss.[7] In S.B.'s case, weight loss could help her decrease or eliminate medications needed to control her hypertension, alleviate pain associated with osteoarthritis, decrease symptoms of sleep apnea, and reduce her BMI and WC, therefore improving her morbidity and mortality risk. In the meantime, her hypertension is currently uncontrolled and should be aggressively managed per the current guidelines.

MANAGEMENT AND TREATMENT

Obesity is a chronic disease that requires lifelong effort for successful treatment.[6,7] Treatment may involve a multidisciplinary approach including the expertise of a general practitioner, dietician or nutrition specialist, pharmacist, psychiatrist, or surgeon depending on the specific needs of the individual. The general goals of weight loss and management are to prevent weight gain, reduce body weight, and maintain weight loss over a long period.

Medical Management

CASE 36-1, QUESTION 4: S.B. reports that she has never received dietary counseling from a medical professional and has always dieted on her own by restricting fat intake. S.B. expresses a desire for weight loss therapy. What are appropriate goals for S.B.'s weight loss? What should the initial treatment plan include?

Weight loss is recommended for patients who have obesity (BMI ≥30) or those who are overweight, who have obesity-related comorbidities or increased waist circumference.[7] An appropriate initial goal for weight loss is 5% to 10% of baseline weight within 6 months.[7] Setting appropriate achievable weight loss goals is important to success; unrealistic expectations for more dramatic weight loss may lead to disappointment and ultimately cause patients to stop any efforts toward weight loss. An appropriate goal for S.B. is 4.55 to 9.1 kg within 6 months. Treatment options to facilitate weight loss include lifestyle interventions and anti-obesity medications. S.B. questioned her physician about weight loss medications, but she has never made an effort to lose weight through a structured weight loss program. The initial treatment plan must always include a reduced calorie diet, increased physical activity, and behavioral modifications. These measures must be attempted and maintained for at least 6 months before considering pharmacotherapy.[7]

Nonpharmacologic Therapy

CASE 36-1, QUESTION 5: S.B. reports that she has never received dietary counseling from a medical professional and has always dieted on her own by restricting fat intake. Although she has not attempted to lose weight recently, S.B. expresses desire to try a program for weight loss and start an exercise regimen. What types of nonpharmacologic therapies are available for weight reduction and relapse prevention?

Comprehensive lifestyle interventions including a calorie- restricted diet, increased physical activity, and behavioral modifications are the foundation of weight loss therapy.

DIET

Diets for weight loss promote caloric restriction. Caloric recommendations for women seeking to lose weight are 1,200 to 1,500 kcal/day and 1,500 to 1,800 kcal/day for men; alternatively, a deficit of 500 to 750 kcal/day is associated with weight loss.[7] Because of the high demand by consumers, there are numerous types of weight loss programs, diets, and products that may or may not be effective for each individual patient. A variety of dietary interventions have been proven successful in weight loss including low-fat diets, higher protein diets, low carbohydrate diets, restricted carbohydrate diets, meal replacement and liquid diets, dietary pattern such as the Mediterranean diet.[7] Research suggests clinically meaningful weight loss is achieved through a reduced calorie diet regardless of the composition of dietary macronutrients.[62]

EXERCISE

Increased physical activity will contribute to the negative energy balance that is required for weight loss. Increased physical activity is essential in preventing weight gain. Overweight children and adults should have at least 30 minutes of moderate-intensity physical exercise daily (with a gradual increment of increasing exercise by several minutes each day up to 30 minutes/day). It has been shown that moderate exercise (e.g., 4 kcal/g/week) can improve physiologic variables.[63,64]

BEHAVIOR THERAPY

The most effective lifestyle intervention includes frequent counseling (>14) group or individual sessions per month with a trained interventionist (registered dietician, nutrition counselor, psychologist, exercise specialist, health counselor, or other trained professional).

Individuals who want to lose weight frequently seek out popular structured programs (e.g., Jenny Craig, Weight Watchers) and these programs have also been proven successful in producing weight loss. Clinical trials that compared dietary interventions conclude that the most effective diet is one that the patient is able to comply with long term.[62,65]

Overall, a combination of a reduced-calorie diet and increased physical activity with support of a trained interventionist is the most effective for reducing and maintaining weight loss. Given that obesity is a chronic condition, S.B. must select a comprehensive lifestyle intervention that is most appealing to her so that she will be able to comply with it long term.

Pharmacologic Therapy

CASE 36-1, QUESTION 6: S.B. returns to her physician for follow-up 6 months later. She has managed to lose 7 kg and is at a weight of 84 kg. Based on her BMI of 29.8 kg/m^2, her weight is classified as overweight. Her depression, osteoarthritis, sleep apnea, and hypertension have improved (current blood pressure is 142/88 mm Hg). Her current medication profile includes bupropion, hydrochlorothiazide, metoprolol, and acetaminophen as needed. Although she has achieved her goal with 7.7% weight loss and is now considered overweight and not obese, S.B. is disappointed that her weight loss has plateaued. She still wants to lose additional weight. She again asks the physician about short-term anti-obesity medications that can help accelerate her weight loss. Would a short-term agent be appropriate for S.B.? What are the mechanisms of action, efficacy, and potential adverse effects of the short-term anti-obesity medications?

As previously stated, a comprehensive lifestyle intervention is the foundation of weight loss management. Although weight loss is possible for most patients, it is not sustainable and regain is common.[66] Obesity is a chronic, lifelong illness that may require long-term medication therapy. Medication should be considered only for patients with a BMI ≥30 kg/m^2 without risk factors or BMI ≥27 kg/m^2 with an obesity-related comorbid medical condition such as hypertension, dyslipidemia, type 2 diabetes, and obstructive sleep apnea (Table 36-2).[6] Medications should not be considered a replacement for diet, behavioral modification, and exercise, but rather as adjunctive therapy. Currently, marketed anti-obesity drugs cause weight loss by suppressing the appetite or decreasing the absorption of fat.[67]

S.B. is a candidate for pharmacotherapy even though her BMI is currently considered overweight at 29.8 kg/m^2, her obesity-related comorbidities of hypertension and sleep apnea qualify her for medication therapy. The most appropriate medication for S.B. must be based on her current medication profile and her comorbid health conditions.

SHORT-TERM THERAPY

Obesity is a chronic disease state; therefore, the clinical usefulness of short-term therapy is unlikely to have a meaningful impact. The FDA has approved several weight loss drugs for short-term use defined as <12 weeks, and these include phentermine, diethylpropion, phendimetrazine, and benzphetamine. All are sympathomimetic agents that function as appetite suppressants.[68,69] Of these drugs, phentermine is the most commonly prescribed and is frequently prescribed, off-label, for long-term therapy.[68]

Phentermine is approved for adjunctive therapy in patients older than 16 years of age, at a dosage of 18.75 to 37.5 mg taken 2 hours after breakfast. Dosing may also be divided into two 18.75 mg doses.[70] The most common adverse effects associated with phentermine therapy are insomnia and dry mouth.[68] Phentermine has also been associated with cardiovascular effects, including case reports of pulmonary hypertension, and as such is contraindicated in patients with cardiovascular disease and hypertension.[71,72] Phentermine also has abuse potential and is considered a controlled substance (schedule IV drug), which further limits its use as a weight loss agent.[69]

Diethylpropion, phendimetrazine, and benzphetamine exhibit appetite suppressive actions similar to phentermine, but are less widely prescribed.[68] They also share adverse effects and contraindications similar to phentermine.[68,69] The abuse potential with these drugs is high, with diethylpropion classified as a schedule IV drug and benzphetamine and phendimetrazine classified as schedule III drugs.[69] Based on their approval for short-term use, adverse effects and abuse potential, none of these agents should be recommended for weight loss therapy.

S.B.'s physician should not prescribe short-term weight loss medications to S.B. Short-term agents for obesity may increase S.B.'s blood pressure. Also short-term agents will not provide the necessary long-term treatment for S.B.'s chronic condition.

CASE 36-1, QUESTION 7: S.B. realizes that her obesity is a chronic condition and inquires about long-term medications for weight loss. What agents are available for the long-term treatment of obesity? (see Table 36-4)

LONG-TERM THERAPY

Orlistat (Xenical, Alli)

Orlistat is FDA-approved for long-term obesity management as an adjunct to lifestyle modification.[73] Orlistat 120 mg was originally marketed under the trade name Xenical. Then, in February 2007, the FDA approved the OTC marketing of orlistat, under the trade name Alli, at a 60 mg dose.[74] Orlistat works to reduce dietary fat absorption by inhibiting GI (stomach and pancreatic) lipase activity.[75,76] Gastric and pancreatic lipase are enzymes that play a pivotal role in the digestion of dietary fat (triglycerides). By inhibiting these lipase enzymes, orlistat prevents the hydrolysis and absorption of triglycerides.[73,77] This results in the excretion of approximately

30% of ingested fat in the feces.[68] Orlistat does not exert appetite suppressant effects, has no CNS effects, and has no systemic absorption.[76] The therapeutic activity of orlistat takes place in the stomach and small intestine and effects are seen as soon as 24 to 48 hours after dosing.

In a meta-analysis, orlistat was shown to produce average weight loss of 2.9 kg or 2.9% greater than placebo.[78] Additionally, a 4-year prospective, double-blind, randomized study, XENDOS, found that orlistat plus lifestyle changes was associated with a 37.3% risk reduction of type 2 diabetes in greater than 3,300 high-risk obese patients.[79] Use of orlistat has also been associated with improvements in blood pressure, as well as improvement in metabolic parameters such as fasting serum lipid profiles and C-reactive protein.[78,80,81]

Table 36-4

Medications for the Treatment of Obesity

Generic Name	Trade Name	Dosing
Orlistat	Xenical	120 mg PO TID
	Alli	60 mg PO TID
Phentermine/topiramate	Qsymia	3.75/23 mg PO QAM × 14 days; then 7.5/46 mg QAM for 12 weeks then evaluate weight loss, if less than 3%, dose may be titrated to 11.25/69 mg QAM × 14 days then 15/92 mg QAM
Lorcaserin	Belviq	10 mg PO BID
Naltrexone/bupropion	Contrave	8/90 mg PO QAM × 1 week then 8/90 mg BID ×1 week then 16/180 mg QAM and 8/90 mg QPM then 16/180 mg BID
Liraglutide	Saxenda	0.6 mg SC daily × 1 week increase dose by 0.6 mg weekly until therapeutic dose of 3 mg daily
Phentermine hydrochloride[a]	Adipex-P	TID; 30–37.5 mg QAM

[a] Not recommended for routine or long-term use.

BID, 2 times a day; OTC, over the counter; PO, by mouth; QAM, every morning; QPM, every evening; SC, subcutaneously; TID, 3 times a day.

The most common adverse effects associated with orlistat include GI problems (loose stools, oily spotting, flatus with discharge, fecal urgency, fatty or oily stools, increased defecation, fecal incontinence, bloating, and cramping).[82] The most common non-GI adverse effect was headache (6%). Side effects usually develop early in treatment and persist for 1 to 4 weeks, but occasionally last longer than 6 months. Because GI adverse effects are worse with a high-fat diet, orlistat may enhance dietary compliance with a low-fat diet. Side effects that continue to be problematic have been associated with nonadherence to orlistat therapy and therefore variability in patient outcomes. Rare cases of oxalate-induced acute kidney injury and liver injury have been reported with use of orlistat.[83,84]

Orlistat may reduce the absorption of fat-soluble vitamins (A, D, E, and K) and patients should take a multivitamin supplement that contains these vitamins.[82] The supplement should be taken once a day at least 2 hours before or after the administration of orlistat, such as at bedtime. Reduced absorption of vitamin K may potentiate the bleeding effects of warfarin. Reduced absorption of vitamin D may lead to metabolic bone disease; supplementation with higher doses of vitamin D may be required.[85] Orlistat may also reduce the absorption of lipophilic drugs including amiodarone, cyclosporine, lamotrigine, and valproic acid.[76,86] Orlistat is contraindicated in pregnancy and in patients with chronic malabsorption syndrome, or cholestasis.[73]

Phentermine/Topiramate ER (Qsymia)

Phentermine/topiramate ER is a combination drug that has been approved by the FDA for long-term obesity management as an adjunct to lifestyle modification.[87] Phentermine is a sympathomimetic agent that functions as an appetite suppressant by increasing the concentration of norepinephrine in the central nervous system.[88] Topiramate is a second-generation antiepileptic agent also approved for the treatment of migraines, which acts as an agonist at γ-aminobutyric acid ($GABA_A$) receptors and as an antagonist at non-N-methyl-D-aspartic acid (NMDA) glutamate receptors.[89] The mechanism by which weight loss occurs with topiramate is unclear, but may be related to a direct action on adipose tissue.[90]

Therapy is initiated at a dose of phentermine 3.75 mg/topiramate 23 mg daily for 14 days, after which the dose is increased to phentermine 7.5 mg/topiramate 46 mg daily. If the patient has not experienced ≥3% weight loss after 12 weeks of therapy at the maintenance dose, the drug should either be discontinued or the dose escalated to phentermine 15 mg/topiramate 92 mg daily. After an additional 12 weeks of therapy, if the patient has not experienced ≥5% weight loss, the drug should be discontinued.[87]

The efficacy of phentermine/topiramate ER has been demonstrated in two phase 3 clinical trials and one expansion trial: CONQUER, EQUIP, and SEQUEL (an extension of the CONQUER trial).[91,92] Phentermine/topiramate ER 7.5/46 mg was shown to produce average weight loss of 7.8% of initial body weight after 1 year and 9.3% after 2 years.[91,93] Phentermine/topiramate ER 15/92 mg was shown to produce average weight loss of 9.8% of initial body weight after 1 year and 10.5% after 2 years.[91,93] Use of phentermine/topiramate ER has also been associated with improvements in cardiometabolic parameters at the 15/92 mg dose.[91,92] Patients taking phentermine/topiramate ER at doses ≥7.5/46 mg also showed reduced progression to type 2 diabetes.[93]

The most common adverse effects associated with phentermine/topiramate ER include paresthesia, dizziness, dysgeusia, insomnia, constipation, and dry mouth.[87] Topiramate has been associated with birth defects, specifically oral clefts when taken during the first trimester, which led the FDA to approve phentermine/topiramate ER with a risk evaluation and mitigation strategy (REMS). This REMS is designed to inform practitioners and patients about the risk of birth defects, the importance of contraceptive use, and the need to immediately discontinue the drug if the patient becomes pregnant.[94] Phentermine/topiramate ER is contraindicated in pregnancy and in patients with glaucoma, hyperthyroidism, MAOI use within the past 14 days, and hypersensitivity to sympathomimetic amines.[87]

Lorcaserin (Belviq)

Lorcaserin is FDA-approved for long-term obesity management as an adjunct to lifestyle modification.[95] It is a selective serotonin 2C (5-HT$_{2C}$) receptor agonist. It is thought that lorcaserin promotes feelings of satiety by activating 5-HT$_{2C}$ receptors in the hypothalamus.[96,97] It is available as 10 mg tablets and is dosed at 10 mg twice daily. If the patient has not experienced ≥5% weight loss after 12 weeks of therapy at the maintenance dose, the drug should be discontinued.[95]

The efficacy of lorcaserin has been demonstrated in three phase 3 clinical trials: BLOOM, BLOSSOM, and BLOOM-DM.[98–100] Lorcaserin was shown to produce average weight loss of 5.8% of initial body weight after 1 year and 7.2% after 2 years.[98,99] Use of lorcaserin has been associated with significant improvements in lipid profiles and glycemic parameters, including reductions in fasting plasma glucose and HbA1c.[98,100]

The most common adverse effects associated with lorcaserin include headache, dizziness, fatigue, nausea, dry mouth, and constipation in patients without diabetes. In patients with diabetes, the most common adverse effects are hypoglycemia, headache, back pain, cough, and fatigue.[95] In the past, nonselective serotonin agonists (fenfluramine and dexfenfluramine) were withdrawn from the market due to adverse cardiac events, most significantly valvulopathy.[98,101] Based on this, the FDA required data on the rates of valvulopathy with lorcaserin; a pooled analysis of the three previously mentioned phase 3 clinical trials found that the rates of echocardiographic valvulopathy were similar in both the lorcaserin and placebo groups.[102] Rarely reported side effects include priapism, hyperprolactinemia, cognitive impairment, hallucinations, and dissociation.[95]

Based on the serotonergic activity of lorcaserin, it is advised to avoid it with other serotonergic drugs such as SSRIs, SNRIs, MAOIs, and triptans.[95] Lorcaserin is an inhibitor of CYP 2D6; caution should be used when co-administering lorcaserin with drugs metabolized by this enzyme. The use of dextromethorphan is of particular concern because it is metabolized by CYP 2D6 and may have serotonergic effects. Lorcaserin is contraindicated in pregnancy.[97]

Naltrexone/Bupropion (Contrave)

Naltrexone/bupropion is a combination drug that has been approved by the FDA for long-term obesity management as an adjunct to lifestyle modification.[103] Bupropion, an antidepressant that inhibits dopamine and norepinephrine reuptake, has a known side effect of weight loss when used for the treatment of depression and smoking cessation.[104] This weight loss effect is thought to be the result of appetite suppression induced by the stimulation of pro-opiomelanocortin neurons in the hypothalamus.[105] Naltrexone, an opioid receptor antagonist, is believed to enhance this appetite suppression by blocking opioid receptors on these same pro-opiomelanocortin neurons.[104] Naltrexone/bupropion is available as combination 8/90 mg tablets. Patients initiate treatment at a dose of one tablet every morning. This dose is titrated up over the course of 4 weeks to a dose of two tablets twice daily, for a total daily dose of 32/360 mg.[21] If the patient has not experienced ≥5% weight loss after 12 weeks of therapy at the maintenance dose, the drug should be discontinued.[103]

The efficacy of naltrexone/bupropion has been demonstrated in four 1-year, placebo-controlled, phase 3 clinical trials: COR-I, COR-II, COR-BMOD, and COR-Diabetes.[103] Naltrexone/bupropion 32/360 mg was shown to produce average weight loss of 6.1% to 6.4% of initial body weight.[106,107] When coupled with intensive behavior modification, patients taking naltrexone/bupropion 32/360 mg experienced an average weight reduction of 9.3% of initial body weight.[104] Use of naltrexone/bupropion has also been associated with improvements in cardiometabolic parameters, including HbA1c reduction.[104,107,108]

The most common adverse effects associated with naltrexone/bupropion include nausea, constipation, headache, vomiting, dizziness, insomnia, dry mouth, and diarrhea.[103] Slight increases in blood pressure and heart rate have been seen in phase 3 clinical trials; thus, these parameters should be monitored during therapy.[103,109] Contrave has a black box warning for suicidal thoughts and behavior, although increased rates have not been seen in phase 3 clinical trials.[103,109] Bupropion is an inhibitor of CYP 2D6; caution should be used when co-administering naltrexone/bupropion with drugs metabolized by this enzyme.[103] Naltrexone/bupropion is contraindicated in pregnancy and in patients with uncontrolled hypertension; seizure disorders; anorexia nervosa or bulimia; sudden discontinuation of alcohol, benzodiazepines, barbiturates, or antiepileptic drugs; chronic use of opioids; use of MAOIs within the past 14 days; and in patients currently taking other bupropion-containing products.[103]

Liraglutide (Saxenda)

Liraglutide, marketed as Saxenda, is an injectable medication, FDA-approved for long-term obesity management as an adjunct to lifestyle modification.[110] When used for obesity, the dose is titrated to 3 mg daily. It is also marketed under the brand name Victoza at a dose of 1.8 mg daily for the treatment of type 2 diabetes.[111,112] Liraglutide is a glucagon-like peptide-1 (GLP-1) receptor agonist. Activation of this receptor acts via the central nervous system to promote feelings of satiety, thereby reducing food intake.[110,113] If the patient has not experienced ≥4% weight loss by 16 weeks after initiating therapy, the drug should be discontinued.[110]

The efficacy of liraglutide for weight loss has been demonstrated in three phase 3 clinical trials: SCALE Maintenance, SCALE Obesity and Pre-Diabetes, and SCALE Diabetes.[114–116] The results have not yet been published for the SCALE Diabetes trial. The results of the SCALE Maintenance trial indicate that by 12 weeks, liraglutide produces an average weight loss of 6.0% greater than placebo.[114] The results of the SCALE Obesity and Pre-Diabetes trial and the data released thus far for the SCALE Diabetes trial indicate that by the end of 56 weeks of treatment, liraglutide produces an average weight loss of 3.9% to 5.4% greater than placebo.[115,116] Use of liraglutide has also been associated with significant improvements in HbA1c, fasting plasma glucose, and fasting insulin.[110,115]

The most common adverse effects associated with liraglutide include nausea, hypoglycemia, diarrhea, constipation, vomiting, headache, decreased appetite, dyspepsia, fatigue, dizziness, abdominal pain, and increased lipase. In order to reduce the incidence of gastrointestinal side effects, liraglutide is initiated at a dose of 0.6 mg daily and titrated up to the effective dose of 3 mg daily over a 5-week-period.[110] Liraglutide has been associated with an increased risk of medullary thyroid carcinoma and acute pancreatitis. As a result, liraglutide is part of a REMS program to ensure practitioners are informed of these risks.[117] Liraglutide is contraindicated in pregnancy and in patients with hypersensitivity to liraglutide or any of its product components, a personal or family history of medullary thyroid carcinoma, or a personal or family history of multiple endocrine neoplasia syndrome type 2.[110]

Investigational Agents

Several recent investigational agents have shown promise in weight loss pharmacotherapy. In a 24-week phase IIb clinical trial, bupropion/zonisamide ER was shown to produce weight loss of 9.9% of initial body weight, as compared to 1.7% weight loss with placebo.[118] Much like naltrexone/bupropion, this combination drug works through a dual mechanism: Bupropion stimulates pro-opiomelanocortin neurons in the hypothalamus, and zonisamide acts synergistically by suppressing an appetite-stimulating neural pathway.[118] The most common adverse events were headache, insomnia, and nausea.[118]

Cetilistat is a lipase enzyme inhibitor, which acts similarly to orlistat, with a more tolerable side effect profile.[119,120] In a 12-week phase II clinical trial, cetilistat produced a mean weight loss of 4.32 kg when taken at a dose of 120 mg 3 times daily by obese patients with diabetes.[120] The most common adverse events were mild-to-moderate GI effects.[54,120]

Tesofensine, an inhibitor of noradrenalin, dopamine, and serotonin reuptake, was initially developed to treat neurodegenerative disease and found to produce weight loss in obese patients with Parkinson's or Alzheimer's disease.[121,122] Early results evaluating this agent for weight loss in combination with caloric restriction have shown dose-dependent reductions in weight up to 10.6% of baseline body weight after 24 weeks of therapy. Adverse reactions associated with tesofensine included nausea, constipation, diarrhea, insomnia, and dry mouth.[125]

Tauroursodeoxycholic acid has also been proposed as a weight loss agent. It is thought to induce weight loss by increasing sensitivity to leptin, a hormone that acts to suppress appetite.[57,123] However, clinical data are lacking at this time.

The most appropriate pharmacotherapeutic option for weight loss depends on patient-specific parameters including other disease states, concomitant medication use, adverse effects, patient preference, and cost. S.B. should avoid agents that will exacerbate her hypertension; therefore, S.B. should not be prescribed phentermine/topiramate and naltrexone/bupropion. Also, S.B. is currently taking bupropion which would duplicate with naltrexone/bupropion and may cause serotonin syndrome with lorcaserin. Orlistat and liraglutide are the only pharmacotherapeutic options for S.B. that can be safely administered with her hypertension and concomitant medication (bupropion). S.B. should chose the most appropriate agent based on her personal preference including her lifestyle (many gastrointestinal side effects and restricted fat intake and multiple daily doses with orlistat) or the subcutaneous route of administration with the liraglutide.

CASE 36-1, QUESTION 8: S.B. began therapy with orlistat 120 mg and lost an additional 8 kg in 6 months. After 6 months, S.B.'s weight loss began to taper and she regained 2 kg such that 1 year later her total net loss is 6 kg. S.B.'s current weight is 78 kg and her BMI is down to 27.6 kg/m^2 but she is disappointed that she has regained weight and inquires about dietary supplements for weight loss. How would you advise SB with regard to dietary supplements? (Table 36-5)

Table 36-5

Dietary Supplements for weight loss

Supplement	Proposed Mechanism	Clinical Data	Adverse Effects and Safety Concerns
Chitosan	A cellulose-type	Meta-analysis (14 trials)	GI effects common

	polysaccharide, reported to bind dietary fat and prevent absorption	demonstrated average placebo-subtracted weight loss of 1.7 kg; average weight loss 0.8 kg in trials lasting longer than 4 weeks	(constipation, diarrhea, flatulence, bloating, nausea, heartburn) Avoid in patients with a shellfish allergy
Caffeine	Increased thermogenesis by inhibiting the breakdown of cAMP	Several clinical trials demonstrate short-term weight loss when used in combination with ephedra (no longer available)	Common adverse effects: insomnia, irritability, tachycardia, anxiety
Green tea	Polyphenols and caffeine act synergistically to decrease fat absorption, reduce lipogenesis, and cause thermogenesis	Several clinical trials demonstrate potential weight loss of up to 2 kg	See caffeine Reports of hepatotoxicity
Guarana (Brazilian cocoa, Paullinia cupana)	See caffeine (seed contains 2.5%–7% caffeine)	See caffeine	See caffeine
Yerba mata (Yerba mate, ilex paraguariensis)	See caffeine	See caffeine	See caffeine Hot drinks may increase risk of esophageal cancer
Citrus aurantium (bitter orange, Seville orange, sour orange)	Contains synephrine (structurally similar to epinephrine)	No evidence of efficacy when used alone; limited data suggest minimal weight loss when used in combination with caffeine and Saint-John's-wort (less than 1 kg weight loss)	Cardiovascular effects (increase heart rate, blood pressure) Reports of angina, increased QT-interval, seizures, and ischemic colitis Potential drug interactions because of inhibition of intestinal CYP 3A4
Hydroxycitric acid (garcinia, Garcinia cambogia)	Theorized to inhibit production of lipids	No evidence of weight loss	Reports of hepatotoxicity, rhabdomyolysis (avoid with statins) May inhibit platelet aggregation
Glucomannan (Konjac)	Fibrous polysaccharide may work similar to fiber (promote/prolong satiety)	Limited data suggest minimal weight loss (1–2 kg)	GI adverse effects (nausea, bloating, flatulence)
Hoodia	Unknown, reported to be an appetite suppressant	No clinical trials to support use	Unknown

cAMP, cyclic adenosine monophosphate; GI, gastrointestinal.

Numerous dietary supplements are marketed for weight loss. Reliable evidence of efficacy for these agents is limited and safety data are lacking. Clinical data do not support the use of these agents and S.B. should be advised not to use dietary supplement for weight loss.

CASE 36-1, QUESTION 9: S.B.'s health insurance changed and she was no longer able to continue orlistat and she slowly regained the lost weight. Two years after discontinuing orlistat, SB has regained 7 kg. Her current weight is 85 kg and her BMI is 30.1 kg/m^2. She is frustrated that she has regained weight despite compliance with comprehensive lifestyle interventions. She asks whether her results are usual and inquires about additional options for weight loss.

S.B.'s regain after discontinuing orlistat is typical. Trials with a crossover design have shown that the weight loss achieved with anti-obesity agents is unlikely to be sustained after discontinuation.[6] Weight regain is to be expected after discontinuing anti-obesity agents because the underlying pathology of obesity is not changed.

Medical Devices for Obesity Treatment

A device called the vBloc Maestro Rechargeable System has been recently approved by the FDA as a treatment option for patients with extreme obesity (BMI ≥40 or ≥35 kg/m^2 with comorbid conditions) who have failed at least one supervised weight management program within the past 5 years.[124] The device is surgically implanted into the abdomen where it emits intermittent electrical pulses to block signaling by the vagus nerve.[124,125] In a recent randomized, double-blind, sham-controlled clinical trial, the vBloc system produced weight loss of 9.2% of initial body weight, compared to weight loss of 6.0% of initial body weight with the sham technology.[126] The most common adverse events were heartburn, dyspepsia, and abdominal pain.[126]

S.B.'s current BMI is 30.1 kg/m^2 which is below the threshold for use of vBloc; therefore, she is not a candidate for a medical device at this time. In order to sustain weight loss, long-term treatment must continue.

CASE 36-1, QUESTION 10: S.B. returns to her physician 3 years later. She has gained an additional 16 kg and her BMI is now 35.4 kg/m^2. She reports inability to maintain her weight with diet and exercise therapy after completion of the behavioral modification program in which she was participating. Laboratory tests provide the following results:

Blood pressure, 154/92 mm Hg
Fasting blood glucose, 162 mg/dL
TG, 354 mg/dL
Total cholesterol, 227 mg/dL
HDL, 35 mg/dL
LDL, 182 mg/dL

S.B. requests a referral to a bariatric clinic for evaluation for surgical intervention for weight loss. Is S.B. a candidate for bariatric surgery? How could a bariatric surgical procedure affect medication administration in S.B. postoperatively?

Surgery

Surgery may be an option for individuals with extreme obesity (BMI ≥40 or ≥35 kg/m^2 with comorbid conditions) who have not responded to lifestyle changes with or without adjunctive pharmacotherapy.[7,127] For severely obese patients (>100% more than normal weight), the most effective treatment is a surgical procedure to reduce the size of the stomach. Bariatric surgical procedures either reduce the absorptive surface of the GI tract resulting in malabsorption, or reduce the stomach volume so that the person feels full after a smaller meal. Procedures include gastric banding, vertical banded gastroplasty, Roux-en-Y gastric bypass, and biliopancreatic diversion; all have demonstrated efficacy, although the degree of weight loss and complications may differ.[128] Gastric bypass has been shown to produce a greater weight loss compared with gastroplasty procedures.[129] In addition, laparoscopic (vs. open surgical) approaches may be preferred for reducing postoperative complications and hospital stay.[128]

The mortality rate from bariatric surgery is estimated to be 0.3% to 1.9% and literature has shown that centers that perform surgeries at high volume have better outcomes.[67] Some of the complications of bariatric surgery include nausea, stomach ulceration, stenosis, anemia, and cholelithiasis. Postsurgical precautions include careful evaluation of meal sizes and timing along with meal content, especially immediately after surgery. Patients should be aware that they will not be able to resume their normal eating habits, and they should be properly educated on lifestyle modifications for maintenance of weight loss. In addition, medications and adequate intake of necessary nutrients are important considerations after surgery. Medications such as nonsteroidal anti-inflammatory drugs, salicylates, and bisphosphonates may cause ulcerations, and medications that are delayed release or extended release may not be absorbed owing to changes in gastric size.[130] Medications may need to be administered using liquid formulation and other dosage routes. Transdermal formulations need to be carefully dosed to account for changes in body surface area postsurgically.[130]

Although S.B. is a candidate for bariatric surgery based on her BMI of 35.4 kg/m^2 and her comorbid conditions (hypertension and sleep apnea), she may also consider alternative pharmacotherapeutic options. S.B.'s fasting blood glucose indicates that she may have type 2 diabetes. Liraglutide is an option that will lower her blood glucose as well as result in clinically significant weight reduction.

Adult Enteral Nutrition

Carol J. Rollins and Jennifer H. Baggs

	CORE PRINCIPLES	CHAPTER CASES
1	Patients should be assessed for the appropriate timing and route for nutrition support.	**Case 37-1 (Questions 1, 2)**
2	The type of tube placement and site of formula delivery are determined by several factors.	**Case 37-2 (Question 1)**
3	Formula selection is based on nutrient requirements, fluid restrictions, and the extent of impaired digestion and absorption.	**Case 37-2 (Questions 2–5)**
4	The administration regimen for feeding is influenced by the feeding route, formula selected, and duration of feeding.	**Case 37-2 (Questions 6–8)**
5	Although the preferred route for nutrition intervention in critical illness is enteral, the ideal formula composition remains unresolved.	**Case 37-3 (Questions 1–4)**
6	Macronutrient content should be considered when selecting an enteral formula for patients with diabetes.	**Case 37-4 (Question 1)**
7	Appropriate monitoring is essential to recognize and prevent complications associated with enteral nutrition.	**Case 37-4 (Question 2)**
8	Medication administration through a feeding tube requires selection of appropriate dosage forms and proper preparation.	**Case 37-4 (Question 3)**
9	Feeding tube occlusion is a common problem influenced by medication-related and nonmedication-related factors.	**Case 37-4 (Question 4)**
10	Patients must meet strict criteria for Medicare coverage of home enteral nutrition.	**Case 37-5 (Question 1)**
11	Diarrhea in patients receiving enteral nutrition is multifactorial, including both tube-feeding-related and nontube-feeding-related causes.	**Case 37-6 (Question 1)**

Enteral nutrition refers to nutrition provided via the gastrointestinal (GI) tract.

However, because the term is commonly used, enteral nutrition (EN) is synonymous with delivery of nutrients into the GI tract by tube (e.g., nasogastric or jejunostomy feeding). Tube feeding allows continued use of the GI tract when one or more steps in the normal process of obtaining nutrients from oral intake are disrupted. Table 37-1 lists functional anatomic units of the GI tract along with major steps occurring in preparing nutrients for absorption and examples of conditions potentially impairing each region. Chewing or swallowing may be completely disrupted, but some digestive and absorptive function must remain for tube feeding to be a viable option.

PATIENT SELECTION AND ROUTE OF FEEDING

CASE 37-1

QUESTION 1: G.W., a 59-year-old woman, 5 feet 2 inches tall, 88 kg, was brought to the emergency department (ED) last night complaining of severe left-sided upper abdominal pain. Tests performed in the ED were consistent with acute pancreatitis. G.W. was admitted to the hospital and has "nothing by mouth" (NPO) orders in her chart. The gastroenterology service has seen her and scheduled an endoscopic retrograde cholangiopancreatography (ERCP) for tomorrow. A nutrition support consult was ordered. G.W. is currently receiving intravenous (IV) 5% dextrose/0.9% sodium chloride with KCl 20 mEq/L at 125 mL/hour. She is also receiving hydromorphone via a patient-controlled analgesia (PCA) pump.

G.W. has been experiencing crampy upper right quadrant pain on and off for about 3 weeks and saw her primary care physician a week ago. She is allergic (rash) to sulfa. She was told that her symptoms are consistent with gallbladder inflammation; surgery will be necessary if her symptoms continue or the pain worsens. In addition, her doctor said blood pressure and glucose control "needed improvement" and mentioned it might be because her weight was up 8 pounds. She quit smoking 6 months ago; she frequently drinks one glass of wine with dinner.

Laboratory values this morning are as follows:

Sodium, 139 mEq/L
Potassium, 3.8 mEq/L
Blood urea nitrogen (BUN), 10 mg/dL
Serum creatinine (SCr), 0.8 mg/dL
Glucose, 175 mg/dL
Albumin, 3.4 g/dL
Amylase, 705 units/L (down from 1,200 units/L in the ED)
Lipase, 698 units/L (down from 1,198 in the ED)
Triglycerides, 185 mg/dL
White blood cells (WBC), 12.7 × $10^3/\mu L$
Hemoglobin (Hgb), 12.4 g/dL
Hematocrit (Hct), 37.3%
C-reactive protein (CRP), 2.2 mg/dL

Does G.W. require nutritional intervention at this time? When should nutrition intervention be considered for G.W.?

Table 37-1

Functional Units of the Gastrointestinal Tract

Functional Unit	Major Steps	Conditions/Diseases Disrupting Function
Mouth and oropharynx	Chew and lubricate food; swallow; taste	Amyotrophic lateral sclerosis, muscular dystrophy, severe RA, CVA, end-stage Parkinson disease, paralysis, coma. Anorexia due to other disease: cardiac or cancer cachexia, renal failure and uremia, liver failure, neurologic disease.
Esophagus	Transport food to the stomach	Esophageal ulcer, cancer, obstruction, or fistula; esophagectomy; CVA.
Stomach	Hold food for mixing and grinding; add acid and enzymes; release chyme to small bowel; osmoregulation	Severe gastritis or ulceration, gastroparesis, gastric outlet obstruction, gastric cancer, severe gastroesophageal reflux.
Duodenum	Osmoregulation; neutralize stomach acid	Severe duodenal ulcer or fistula; cancer: gastric or pancreatic; surgical resection or bypass of the duodenum: Whipple-type procedures.
Small bowel: jejunum and ileum	Digestion; absorption	Enterocutaneous fistula, severe enteric infection, malnutrition, malabsorption, Crohn disease, celiac disease, ileus and dysmotility syndrome.
Pancreas	Secretion of digestive enzymes	Pancreatitis, pancreatic cancer, pancreatic injury, pancreatic fistula.
Colon	Absorb fluid; ferment soluble fiber and unabsorbed carbohydrate; absorb water	Ulcerative colitis, Crohn disease, colon cancer, colocutaneous fistula, colovaginal fistula, diverticulitis, colitis of any etiology, colon surgery.

CVA, cerebrovascular accident; RA, rheumatoid arthritis.

Patients generally are considered at risk for nutrient depletion and associated increased morbidity and mortality when intake is less than 50% to 75% of requirements for 5 to 7 days acutely or when weight loss exceeds 5% or more in 1 month, 7.5% or more in 3 months, or 10% or more of pre-illness weight within a 6-month period.[1,2] For adequately nourished patients, specialized nutrition support is generally not warranted when support will be needed for fewer than 7 to 10 days.[3] Undernourished patients require nutritional intervention sooner. See Chapter 35, Basics of Nutrition and Patient Assessment, for further information on malnutrition. G.W. was adequately nourished before admission based on her weight for height and serum albumin. She has weight gain per the clinic visit, although edema should be ruled out as a cause, and has been NPO for less than 24 hours. Nutrition support is not warranted at this time. However, once the ERCP has been completed, the need for nutrition intervention should be reassessed. If G.W. must remain NPO for a week or more, nutritional intervention would be warranted. Obesity does not preclude the need for nutritional intervention.

CASE 37-1, QUESTION 2: What route of nutrition intervention would be most appropriate for G.W. if she cannot restart her diet in a timely manner?

Routes of nutrition intervention may include modified oral diet, including oral supplements or altered consistency diets (e.g., thickened liquids, pureed foods), EN by tube, or parenteral nutrition (PN). Tube feeding is considered the route of choice in patients with a functional GI tract in whom oral nutrient intake is contraindicated or is insufficient to meet estimated needs.[3] Other than potential "gallstone" pancreatitis, G.W. is expected to have a functional GI tract. The ERCP and pain symptoms will help determine whether G.W. will remain NPO or have a diet started. It appears her pancreatitis is improving based on decreasing amylase and lipase values. For patients with severe acute pancreatitis, Society of Critical Care Medicine (SCCM) and American Society for Parenteral and Enteral Nutrition (ASPEN) Critical Care (SACC) guidelines recommend initiation of EN as soon as volume resuscitation is complete.[4] For patients such as G.W. with mild-to-moderate acute pancreatitis, symptoms typically resolve before nutrition intervention is necessary. When symptoms are prolonged and nutrition support is required, EN is the preferred route of nutrition support because EN may reduce the inflammatory response and decrease complications.[4–6]

EN may be appropriate for patients with the disorders listed in Table 37-1, depending on the extent to which normal intake, transport, digestion, and absorption of nutrients are impaired. Clinical circumstances, not specific diagnoses, should be the determining factor for initiating tube feeding. EN should be used with caution in patients with severe necrotizing or hemorrhagic pancreatitis, distal high-output enterocutaneous fistulae, hypotension with significant inotropic support, GI ischemia, and partial bowel obstruction.[3,4] Contraindications to EN generally include diffuse peritonitis, complete bowel obstruction, severe paralytic ileus, intractable vomiting or diarrhea, severe malabsorption, severe GI bleed, inability to access the GI tract, and when aggressive intervention is not warranted or desired. Frequent reassessment is recommended because patients may become candidates for EN as the condition improves or resolves.

FEEDING TUBE PLACEMENT AND SITE OF FORMULA DELIVERY

CASE 37-2

QUESTION 1: D.S., an 80-year-old man, was hospitalized 7 days ago after collapsing while grocery shopping. He was diagnosed with ischemic stroke, and his condition has changed little since admission. D.S. is estimated to be 5 feet 10 inches tall; his weight is 62 kg; clinic notes from 6 months ago show his weight at 69.3 kg. He appears thin with mild wasting of arm and leg muscles. His maintenance IV drip is 5% dextrose/0.45% sodium chloride with KCl 10 mEq/L at 80 mL/hour. Laboratory evaluation today shows the following:

Sodium, 141 mEq/L
Potassium, 3.7 mEq/L
Chloride, 106 mEq/L
Glucose, 88 mg/dL
SCr, 0.9 mg/dL
Serum albumin, 3.2 g/dL

D.S. failed his swallow study today and will remain NPO for 7 weeks prior to a repeat swallow study, which he must pass before an oral diet is initiated. Nutrition support via tube feeding is ordered.

What is the most appropriate type of feeding tube placement and site for formula delivery?

The type of tube placement and site of formula delivery for EN are determined by the anticipated duration of tube feeding, disrupted region or process in the GI tract, and the risk of aspiration. Figure 37-1 illustrates the two basic types of tube placement—nasal versus ostomy—and the sites available for formula delivery (i.e., gastric, duodenal, or jejunal). The name of the feeding route usually includes both the type of tube placement and the site of formula delivery. For example, nasogastric (NG) indicates nasal placement with gastric delivery of formula, whereas gastrostomy indicates ostomy placement with gastric delivery of formula.

Nasal tube placement is preferred for short-term use in patients expected to resume oral feeding and without obstruction of nasal, pharyngeal, or esophageal passages. The tube is secured to the nose or cheek after placement to prevent the tube from being displaced.

Clinically evident injury from nasal intubation is very low, but patients may suffer mucosal trauma in the nasopharynx.[7–9] Pharyngitis, sinusitis, otitis media, and incompetence of the lower esophageal sphincter are associated with nasal tubes, especially large-bore tubes. The incidence of inadvertent pulmonary placement of small-bore feeding tubes is 4% or less.[7] Radiographic confirmation of tube placement is mandatory to rule out pleural perforation and pulmonary intubation in unconscious patients and remains the standard to ensure correct tube placement in all patients. Tube displacement is a potential complication occurring in 25% to 41% of cases.[7]

Feeding ostomies (tube enterostomies) generally are reserved for long-term EN, interpreted as anywhere from 4 weeks to 6 months, depending on clinical circumstances and the type of tube enterostomy placed. Access for enterostomies can be achieved through open surgery, laparoscopy, or via percutaneous access. Percutaneous access is usually performed under local anesthesia or conscious sedation by endoscope (percutaneous endoscopic gastrostomy [PEG] or jejunostomy [PEJ]) or by radiography (percutaneous radiologic gastrostomy [PRG] or jejunostomy), including fluoroscopy, ultrasound, or computed tomography.[7,10,11] The major advantage of radiologic compared with endoscopic placement is reduced contamination of the puncture site by oral pharyngeal microorganisms, which are implicated in the 5.4% to 30% incidence of site infections.[9] Most patients requiring long-term EN receive either a PEG or a PRG. Less than 5% receive a combined gastric and jejunal access (PEGJ or G-J) tube.[12]

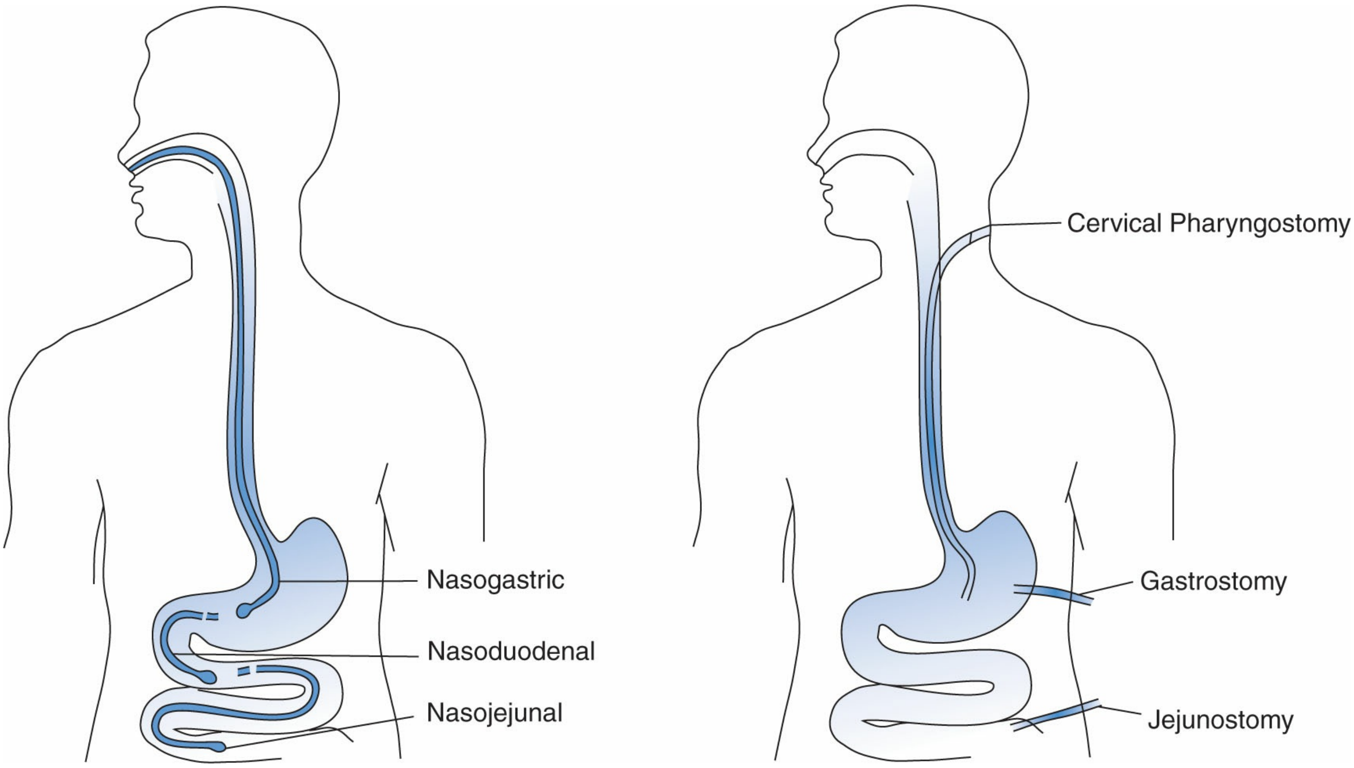

Figure 37-1 Nasoenteric and enterostomy feeding sites.

Endoscopic placement is contraindicated when obstruction prevents passage of the endoscope, but radiographic placement may be possible in such cases. Relative contraindications to percutaneous feeding tube placement include inability to see the endoscopic light through the abdominal wall (e.g., morbid obesity, massive ascites), peritoneal dialysis, coagulopathy, gastric varices, portal hypertension, hepatomegaly, and neoplastic or infiltrative disease of the gastric or jejunal wall.[7–11],[13] Prior total or subtotal gastrectomy, including Roux-en-Y gastric bypass and gastric sleeve for obesity reduction, prevents percutaneous gastrostomy placement, but percutaneous jejunostomy may be possible. Major advantages of percutaneous access are shorter procedure time and lower cost; morbidity and mortality appear to be similar to surgical feeding tube access.[13] Major complications, such as aspiration, peritonitis, hemorrhage, gastrocutaneous fistula formation, necrotizing fasciitis, gastric perforation, and migration of the tube through the gastric wall, are generally low but have been reported in up to 2.5% of patients.[7]

Formula delivery into the stomach is preferred because it is the most physiologically normal feeding site. Stimulation of normal digestive processes and hormonal responses associated with eating occur. The stomach serves as a reservoir, typically allowing tolerance of bolus, and intermittent or continuous feeding. Gastric feeding requires adequate gastric motility to prevent accumulation of formula in the stomach. Patients with gastric outlet obstruction, gastroparesis, gastric distension, or gastroesophageal reflux are poor candidates for gastric feeding.

Postpyloric feeding into the duodenum or jejunum may be appropriate when gastric dysfunction or disease is present, for early postoperative feeding when gastric emptying may be impaired, when pancreatic stimulation is to be minimized, or when risk of aspiration is high. Critically ill patients are at risk for aspiration and ventilator-associated pneumonia, with a 25% to 40% incidence of aspiration in patients with long-term nasoenteric feeding.[14] Evidence of reduced aspiration and improved outcomes with postpyloric feeding remains controversial.[4] A study in 428 patients using pepsin as a marker of aspiration showed steady decline in the pepsin positive samples moving from stomach (34.4%) to proximal, mid-, and distal duodenum (20.8%, 17%, and 7.6%, respectively).[15] Conversely, a meta-analysis of 17 randomized, controlled trials failed to find a benefit of postpyloric feeding on aspiration risk and ventilator-associated pneumonia.[16] Poor differentiation between aspiration of oral secretions and aspiration from the GI tract occurs in many studies; however, this is avoided by using pepsin as a marker. Tube placement beyond the ligament of Treitz (into the jejunum) may be best for patients at risk of tube migration and aspiration; however, studies are not conclusive, and either gastric or small bowel feeding is considered acceptable in the intensive care unit (ICU) setting.

D.S. will require EN for at least 7 weeks and may require longer-term EN depending on repeat swallow study results. A feeding ostomy is appropriate for him. Because there does not appear to be a contraindication to feeding into the stomach, a gastrostomy is appropriate. He will likely have a PEG or PRG placed to avoid the need for surgery.

FORMULA SELECTION

CASE 37-2, QUESTION 2: What factors should be considered in selecting an enteral formula for D.S.?

Enteral formula selection is based on nutrient requirements, fluid restrictions, and the extent of impaired digestion and absorption. Many enteral formulas are available, but because of similarities between products, institutional formularies are generally limited but still provide an adequate selection to meet a variety of patient needs. Categorizing formulas as listed in Table 37-2 simplifies the formula selection process. There are three major categories of enteral formulas: (a) polymeric formulas, (b) oligomeric formulas, and (c) specialized formulas.

Polymeric Formulas

Polymeric formulas are designed for patients with full digestive capability and are used most often. Osmolality is decreased and palatability increased in these formulas by the use of relatively intact nutrients, including whole (i.e., intact) proteins. Administration of approximately 1.5 to 2 L of most polymeric formulas provides 100% of dietary reference intakes (DRI) for vitamins and minerals; thus, these formulas sometimes are called "complete" formulas.[17] As indicated in Table 37-2, the relative cost for polymeric formulas tends to be less than that of oligomeric or specialized formulas, although prices can vary considerably based on specific nutrient content (e.g., omega-3 fatty acids [ω-3FAs], antioxidants).

Oligomeric Formulas

Oligomeric formulas, also called predigested, monomeric, or chemically defined formulas, are designed for patients with reduced digestive function. Pancreatic enzyme activity is required for digestion of oligosaccharides (carbohydrates) and fats. Brush-border disaccharidase activity also is required. Minimal digestion is required, however, for the hydrolyzed protein and medium-chain triglyceride (MCT) components. These formulas can be used for patients with pancreatic insufficiency, reduced mucosal absorption, or reduced hydrolytic capability. Although the Canadian Clinical Practice (CCP) guidelines noted patients with GI complications, such as short bowel syndrome and pancreatitis, may benefit from oligomeric formulas, insufficient data were available to make recommendations regarding use of such formulas.[18–20] Pancreatic enzyme supplementation combined with polymeric formulas may be tried before oligomeric formulas for some patients with pancreatic insufficiency (e.g., cystic fibrosis, chronic pancreatitis).

Two subgroups of oligomeric formulas can be differentiated based on the protein source. True "elemental" formulas contain free amino acids, whereas "peptide-based" formulas contain oligopeptides plus dipeptides, tripeptides, and free amino acids from hydrolysis of protein. Amino acids require no digestion, but the sodium-dependent active transport mechanism is somewhat slow and inefficient with only about one-third of dietary protein absorbed as free amino acids; the remaining two-thirds are absorbed as dipeptides and tripeptides.[21,22] Specific carriers for dipeptide and tripeptide absorption, located in small bowel mucosa, do not compete with the free amino acid transport system. Peptides longer than three amino acids require further hydrolysis within the lumen of the small bowel before they are absorbed. Most peptide-based formulas contain a significant portion of peptides requiring hydrolysis before absorption. No well-designed, randomized, controlled trials have clearly delineated clinical differences in elemental (free amino acid) versus peptide-based formulas. Elemental formulas generally have the lowest-fat content (10% or less of calories from fat). Peptide formulas typically contain one-fourth to one-third of calories from fat, but provide 20% to 70% of the fat as MCT to minimize the risk of malabsorption.

Oligomeric formulas are typically hypertonic owing to their partially digested nature; peptide-containing formulas are typically less hypertonic than free amino acid products. Osmotic diarrhea can occur because of the hyperosmolality; however, the CCP guidelines meta-analysis found no difference in diarrhea occurrence between patients receiving intact protein and those receiving peptide-rich formulas.[18] Taste and cost are disadvantages of oligomeric formulas. Flavoring packets are available and newer formulas may be better accepted, but patients commonly complain of a bitter taste when these formulas are taken orally. In general, patients do not tolerate adequate oral consumption of an oligomeric formula. As shown in Table 37-2, the cost of oligomeric formulas tends to be greater than 10 times the cost of polymeric formulas.

Table 37-2

Generic Groups and Subgroups of Enteral Formulas with Relative Costs

Type of Formula	Relative Cost[a],[b]	Examples
Polymeric Formulas[c]		
Standard Caloric Density, Standard (or High Nitrogen) Content with Varied Fiber Content		
Fiber free for oral supplement or tube feeding	$	Ensure; Nutren 1.0
Low fiber (from 1– g/1,000 kcal)	$	Nutren Probalance[d]
Moderate fiber (>9–<14 g/1,000 kcal)	$	Ensure with fiber; Fibersource HN[d]
High fiber (≥14 g/1,000 kcal)	$	Glucerna; Jevity 1.2 Cal[d]; Nutren 1.0 with fiber
Standard-Nitrogen Content, Fiber-Free (or Low Fiber) with Varied Caloric Density		
Standard caloric density (1–1.2 kcal/mL)	$	Ensure; Nutren 1.0
Moderate density (1.5 kcal/mL)	$	Boost Plus; Ensure Plus; Isosource 1.5 Cal[e]; Nutren 1.5
Calorically dense (1.8–2 kcal/mL)	$	Nutren 2.0
Standard Caloric Density, Fiber-Free with Varied Nitrogen (Protein) Content		
Low nitrogen (6%–10% of kcal as protein)	$	Resource Breeze
Standard nitrogen (11%–16% of kcal as protein)	$	Ensure; Nutren 1.0
High nitrogen (17%–20% of kcal as protein)	$	Isosource HN; Osmolite 1.2 Cal

Very high nitrogen (>20% of kcal as protein)	$$	Boost High Protein; Promote; Replete
Oligomeric Formulas		
Elemental (free amino acids)[f]	&&	f.a.a.; Tolerex; Vivonex T.E.N.
Peptide Based		
Standard protein	&	Peptamen; Peptamen with Prebio
High protein	&	Peptamen 1.5
Very high protein (NPC:N <100:1; >20% calories as protein)	&&	Crucial; Peptamen AF
Specialized Formulas		
Renal Failure

Polymeric, low electrolyte (less than standard potassium, phosphorus, and magnesium)	$$$$	
■ Low nitrogen		Suplena
■ Standard nitrogen		Novasource Renal
■ High nitrogen (for dialysis)		Nepro
Hepatic failure (high BCAA, low AAA[f])	&&&&	Nutrihep
Stress or Critically Ill		
Branched-chain enriched	&&&	
High nitrogen plus conditionally essential nutrients	$$	
Immune modulating	&&	Oxepa
Pulmonary disease (standard; not IMP)	$$	Nutren Pulmonary; Pulmocare
Glucose control	$$$	Diabetisource AC; Glucerna; Nutren Glytrol

[a] Based on average cost per 1,000 calories for equivalent formulas on a University Health System contract from 2010 to 2013.

[b] Index product is a standard caloric density, standard-nitrogen content, fiber-free formula. Cost is indicated relative to an index product given a value of 1:
$ = same cost as index product, up to 1.5 times that cost per 1,000 calories.
$$ = cost is 1.6 to 2.5 times the cost of the index product per 1,000 calories.
$$$ = cost is 2.6 to 3.5 times the cost of the index product per 1,000 calories.
$$$$ = cost is 3.6 to 4.5 times the cost of the index product per 1,000 calories.
& = cost is 11 to 15 times the cost of the index product per 1,000 calories.
&& = cost is 16 to 20 times the cost of the index product per 1,000 calories.
&&& = cost is 20 to 24 times the cost of the index product per 1,000 calories.
&&&& = cost is 25 to 30 times the cost of the index product per 1,000 calories.

[c] All products listed in the table are lactose-free.

[d] High nitrogen.

[e] Low fiber.

[f] Special order, not on formulary used for price calculations.

AAAs, aromatic amino acids; BCAAs, branched-chain amino acids; IMP, immune-modulating pulmonary; NPC:N, nonprotein calorie to nitrogen ratio.

Specialized Formulas

Specialized formulas are designed for specific disease states or conditions; however, clinical benefits are often controversial. Formulas generally have a good theoretic basis for use, yet many lack conclusive clinical evidence of improved efficacy compared with standard formulas. Well-designed studies showing a difference in outcome between specialized and standard enteral formulas providing equal nitrogen and equal calories are limited for most types of specialized formulas. As shown in Table 37-2, there are several different types of specialized formulas; costs and evidence for use vary greatly among them.

D.S. requires EN because he cannot adequately protect his airway when swallowing. There is no evidence presented to suggest he has problems with digestion or absorption. One of the polymeric formulas on the hospital EN formulary should be selected for D.S. The choice of polymeric formula can be narrowed by several factors, including requirements for calories, protein, fluid and fiber, as well as potential nutrient intolerances.

CASE 37-2, QUESTION 3: What are D.S.'s requirements for calories, protein, and fluid? Does he have any special nutrient requirements?

D.S.'s nutrient requirements must be assessed before proceeding in the selection of enteral formula. Based on his weight–height ratio, 10% weight loss over 6 months, slightly elevated CRP, and mild muscle wasting D.S. has moderate malnutrition in the context of chronic illness. Low serum albumin is a risk factor for morbidity and mortality, but is not a reliable indicator of nutritional status.[2] Weight loss to 85% of ideal body weight ([IBW], 73 kg) most likely is due to chronic deficiency in total energy intake, but may also be associated with significant loss of lean mass, especially in older men.[23]

Because D.S. has an IBW less than the ideal for his height, his actual weight should be used to estimate energy and protein requirements. Use of IBW to estimate requirements for undernourished patients may result in fluid and electrolyte imbalance. Once the patient is stabilized on nutrition support, calories can be increased, if necessary, to achieve weight gain.

D.S.'s level of metabolic stress is relatively low. He has no surgical wounds, fractures or skeletal trauma, burns, or major infections, although CRP indicates mild inflammation. Caloric requirements are only slightly higher than basal needs.

Although the term calorie is used interchangeably with kilocalorie (kcal) in nutrition literature, the large “Calorie” or kilocalorie technically is correct and energy requirements generally are listed as kcal/day or kcal/kg body weight when specific numbers are given for a patient. See Chapter 35, Basics of Nutrition and Patient Assessment, for methods of determining nutrient requirements. An estimation of 20 to 25 kcal/kg actual weight can be used based on D.S.’s low level of metabolic stress, but higher caloric intake (25–30 kcal/kg/day) may be needed for weight gain after he is stable.

Protein requirements for healthy elderly people are controversial but estimated to be 1 to 1.2 g/kg/day, which is higher than the DRI of 0.8 g/kg/day.[24] D.S.’s protein needs are estimated to 1 to 1.2 g/kg actual weight per day, minimum, based on inflammation and chronic malnutrition. Renal function appears adequate for D.S. to tolerate 1.2 g/kg/day without experiencing azotemia. SCr, however, may provide a poor estimate of renal function in underweight patients owing to less-than-normal muscle mass.

Daily fluid requirements for geriatric patients can be estimated at 30 mL/kg or 1 mL/kcal ingested, with a minimum of 1,500 mL daily, plus replacement of excess losses from hyperthermia, vomiting, or diarrhea.[24] Baseline requirements of 1,500 mL for the first 20 kg plus 20 mL per each additional kilogram of body weight also can be used to estimate fluid requirements. D.S. does not appear to have any excess fluid losses at this time; therefore, calculation of baseline fluid requirements should provide adequate fluids.

D.S.’s estimated daily requirements are approximately 1,240 to 1,550 total calories, 62 to 74 g protein, and about 1,860 mL of fluid. These are estimated requirements that should be adjusted based on frequent reassessment of D.S.’s response to therapy and changes in his clinical situation. Additional calories and protein may be needed for repletion of weight and protein status.

D.S.’s apparently suboptimal nutrition before hospitalization increases his risk for vitamin deficiencies (see Chapter 35, Basics of Nutrition and Patient Assessment). Medical, medication, and dietary histories should be evaluated to determine nutritional risks associated with specific conditions. D.S.’s age, along with his acute illness and chronic malnutrition, increases his risk of vitamin deficiencies, and he may have at least some subclinical deficiencies. He should receive 100% of the DRI, minimum, for vitamins and minerals daily.[17] If actual deficiencies are identified, D.S. will require higher, therapeutic doses for the specific vitamins that are deficient.

D.S. may be at risk of refeeding syndrome. His weight is low (85% of IBW), although his body mass index is acceptable at 19.5 kg/m^2. Chronic malnutrition can lead to intracellular depletion of potassium, phosphorus, and magnesium, whereas serum concentrations are maintained. When specialized nutrition support begins, refeeding syndrome may develop as these electrolytes move from the extracellular space into the cells, causing a decrease in serum concentrations during the first few days of feeding.[25] Failure to monitor the patient and replace electrolytes as necessary can result in serious electrolyte abnormalities. Knowing D.S.'s weight history, particularly recent weight loss, and his diet history could help assess his potential for clinically significant electrolyte and fluid abnormalities associated with refeeding syndrome.

CASE 37-2, QUESTION 4: Which category of polymeric formulas would be most appropriate for D.S. based on his estimated nutritional requirements?

Polymeric formulas can be divided into several categories based on nutrient sources, caloric density, and protein content. Each category should be evaluated because formula characteristics overlap between the categories.

NUTRIENT SOURCE

Polymeric formulas can be subdivided based on lactose content. Hospitalized patients are presumed to be lactose intolerant due to reduced disaccharidase production during fasting, malnutrition, and various GI tract diseases.[26,27] In addition, most ethnic groups, except northern Europeans, have reduced lactase production in adulthood, leading to lactose intolerance. Lactose ingestion can cause bloating, flatulence, abdominal cramps, and watery diarrhea in patients with permanent or transient lactose intolerance. Lactose-free formulas are the standard for tube-fed adults. Most enteral products are lactose-free, except the powdered products reconstituted with milk and generally intended for oral consumption. Proteins, even those derived from milk, do not contribute to lactose content because lactose is a carbohydrate. The majority of enteral formulas are also gluten-free to avoid GI symptoms associated with celiac disease.

Table 37-3

General Descriptions of Macronutrient Quantity in Enteral Formulas

	Low	Standard	Moderate	High	Very High
Caloric density (kcal/mL)	<1	1–1.2	1.5	1.8–2	>2
Free water (%)	65%–75%	80%–85%	75%–80%	>85%	
Nitrogen (protein) content: % kcal as protein	6%–10%	11%–16%		17%–20%	>20%
Nitrogen (protein) content: NPC:N	>200:1	200:1–130:1		125:1–100:1	<100:1
Fiber content (g/1,000 kcal)	1–9	None	>9–<14	≥14	

NPC:N, nonprotein calorie to nitrogen ratio.

CALORIC DENSITY

Caloric density influences the volume of formula needed to meet nutrient requirements. Standard caloric density is 1 to 1.2 kcal/mL. Table 37-3 lists the general descriptions for caloric density and macronutrient quantities in enteral formulas. Increased caloric density increases formula osmolality. Gastric emptying can be reduced when osmolality exceeds 800 mOsm/kg and this may result in feeding intolerance.[28] GI intolerance (e.g., nausea, flatulence, abdominal discomfort) also can occur if the capacity of intestinal enzymes is overwhelmed by infusion of a calorically dense formula.

Caloric density reflects the free-water content of EN formulas. Risk of dehydration increases with increasing caloric density; however, standard caloric density formulas can result in fluid overload in patients with congestive heart failure, renal failure, or other fluid-sensitive conditions. Calculation of water provided by EN helps determine the volume of additional fluid needed to meet daily fluid requirements. Free-water content is generally 80% to 85% (800–850 mL/L of formula) for formulas with 1 to 1.2 kcal/mL. Table 37-3 lists free-water content associated with other caloric densities. The available history for D.S. does not suggest a need for fluid restriction; therefore, it would be reasonable to initiate feedings with a standard caloric density product (1–1.2 kcal/mL).

PROTEIN CONTENT

Protein needs increase disproportionately to caloric needs during injury and critical illness, whereas protein tolerance may limit protein provision in other conditions. To meet the need for varying ratios between calories and protein, polymeric formulas are available with a range from low- to very high protein content. Either percentage of calories from protein or nonprotein calories to nitrogen (NPC:N) ratio can be used to define protein content. Table 37-3 lists general descriptions for protein content. High-nitrogen enteral formulas are designed for patients with an increased protein requirement without a proportional increase in caloric needs. Very high nitrogen formulas are generally intended for critically ill patients or those with large wounds to heal. Low-nitrogen formulas are available for patients requiring protein restriction. Some low-nitrogen formulas are designed for patients with reduced renal function and can be classified as specialized formulas.

D.S. could obtain adequate protein from a formula with standard protein content. A formula with slightly higher-protein content (17%–18% of calories) would also be acceptable. A high-nitrogen formula that meets D.S.'s calorie needs will provide protein at the upper end of the estimated requirement (1.2 g/kg/day), whereas a standard-nitrogen formula will provide between 0.8 and 1 g/kg/day. A high-nitrogen formula may replete D.S.'s somatic and visceral protein status sooner but it may not provide adequate calories for weight gain. The decision to use a high-nitrogen versus standard-nitrogen formula depends on the exact nutrient composition of products on the EN formulary.

CASE 37-2, QUESTION 5: Should the EN product selected for D.S. contain fiber and if so, what type and amount?

Fiber has potential physiologic benefits, including increased fecal bulk, decreased bowel transit time in patients susceptible to constipation, increased transit time in patients with diarrhea, reduction of serum cholesterol, and improved glycemic control in patients with diabetes. Recommended daily fiber intake for healthy Americans is 21 to 25 g for women and 30 to 38 g for men, with the lower end of these amounts for people 51 years of age or older.[29] Adequate intake is determined by calorie intake and fiber intake observed to protect against coronary artery disease (14 g/1,000 calories). Optimal fiber intake for ill persons has not been determined. Fiber-supplemented formulas vary considerably in fiber content. There is no standardized terminology for low-fiber, moderate-fiber, and high-fiber content; however, the amounts listed in Table 37-3 can serve as a general guideline.

Enteral formulas may contain either insoluble or soluble fiber, or both. Insoluble fiber is associated with changes in fecal bulk and transit time, whereas soluble fiber tends to be responsible for effects on cholesterol and glycemic control. Soluble fibers, such as pectin, psyllium, and certain gums, tend to form gels and are used as a single fiber source only for low-fiber formulas. Fructooligosaccharides (FOS) are naturally occurring sugars that are added to some enteral formulas for soluble fiber benefits with better formulation characteristics (i.e., less gelling). Soluble fibers and FOS can be fermented to short-chain fatty acids by Bifidobacterium in the colon.[30,31] Short-chain fatty acids stimulate colonic blood flow, enhance fluid and electrolyte absorption, and provide a trophic effect in the colon.

The most common fiber source for enteral formulas is soy polysaccharide, or soy fiber. Although soy polysaccharide demonstrates beneficial effects associated with both soluble and insoluble fibers in healthy subjects and non-critically ill patients, studies do not provide clear evidence of improved bowel function in critically ill patients.[31] Routine use of fiber is not supported by available data in critically ill patients.[18–20] Given available data, stable patients on long-term EN appear most likely to benefit from fiber-supplemented formulas. Some patients on short-term EN without GI pathology who experience altered stool consistency may benefit from fiber supplementation.

Addition of fiber to enteral formulas creates some potential problems. Fiber increases viscosity and fiber-containing formulas often require a pump for administration through feeding tubes. GI symptoms from fiber can include increased gas production and abdominal discomfort.[27,31] Improvement in constipation has been noted with FOS administration; however, intake of greater than 45 g/day may cause diarrhea.[32] Flatulence and bloating can limit tolerance to FOS for some patients. Gradual introduction of fiber may help reduce these symptoms. Bezoar formation also has been reported in a patient receiving fiber-containing tube feedings and medications that suppressed GI motility.[31] Caution is advised for the use of fiber-containing formulas in patients with poor GI motility and underlying GI dysfunction. Insoluble fiber should be avoided in critically ill patients, and patients at high risk of bowel ischemia or severe dysmotility should not receive either soluble or insoluble fiber.[4] Inadequate fluid intake may also contribute to the risk of bezoar formation and intestinal blockage with fiber.

D.S. is not critically ill and does not appear to have bowel pathology precluding use of a fiber-containing formula. He will require EN for a moderate duration of time and potentially long term. It would be reasonable to provide a formula with at least moderate fiber content. However, D.S. could experience GI symptoms from the fiber, especially if his diet has previously been of low-fiber content. If necessary, a low-fiber formula could be used initially and then transitioned to higher fiber once symptoms of bloating and gas improve.

CASE 37-2, QUESTION 6: What is an appropriate administration regimen for D.S.'s tube feeding?

The feeding route, formula selected, and anticipated duration of feeding influence the administration regimen. Patient location (e.g., hospital, nursing facility, home) and cost also are considered when developing the regimen, including the rate for initiating and advancing feedings, and the administration method (i.e., syringe, gravity drip, pump).

Limited scientific data exist regarding EN administration regimens; thus, expert opinion plays an important role and different regimens can be used in various settings, all of which appear to meet the needs of the patients and personnel. The administration regimen should be adjusted as necessary for feeding intolerance. Four basic schedules for formula delivery are available: (a) continuous infusion, (b) cyclic infusion, (c) intermittent infusion, and (d) bolus delivery of formula.

Continuous Infusion

Continuous infusion provides formula at a continuous rate for 24 hours/day and can be used with any route of feeding. Intragastric continuous infusion is most commonly used for hospitalized patients, although small bowel feeding may be more appropriate in certain settings (e.g., ICU).[18–20] Risks of gastric distension and aspiration may decrease with continuous infusion compared with intermittent gastric infusion.[14] In addition, the slower infusion rate associated with continuous infusion may be better tolerated as judged by stool frequency and time to attain full nutrition support, especially in the elderly and in metabolically unstable patients.[33–35] However, data were insufficient to include a recommendation for continuous infusion versus other administration methods for critically ill patients in the CCP guidelines.[18–20] Feeding into the duodenum or jejunum is best initiated with continuous infusion because rapid infusion of large formula volumes into the small bowel can result in symptoms of dumping syndrome, including sweating, lightheadedness, abdominal distension, cramping, hyperperistalsis, and watery diarrhea. With time, the jejunum may adapt to larger volumes over a shorter time allowing cyclic or longer intermittent infusions.

Cyclic Feeding

Cyclic feeding provides formula at a continuous rate for less than 24 hours daily. This method is most commonly used for patients who need supplemental nutrition because of an inability to consume adequate oral nutrients, during transition to an oral diet, and for long-term home EN patients. Infusions are typically given at night for 8 to 12 hours to minimize interference with oral intake and normal activities during the day, although cycles can be as long as 20 hours. Most patients do not start on a cyclic regimen; rather, they transition from continuous feeding. Formula volume and osmolality can limit tolerance to cyclic feedings, especially jejunal feedings, and transition from continuous to cyclic infusion may require several days to weeks depending on patient tolerance. For gastric feeding, the transition usually takes only a few days.

Intermittent and Bolus Feedings

Formula is provided in three to eight gastric feedings daily for intermittent and bolus administration. Intermittent infusion occurs for 30 to 60 minutes using a feeding container or bag, with or without an enteral pump, and bolus feedings are for about 15 minutes using gravity administration via a syringe.[34–37] The stomach's reservoir capacity allows administration of relatively large volumes on an intermittent or bolus schedule. This is more physiologic than continuous feeding and more convenient for patients in nursing facilities and ambulatory patients at home on EN.

INITIATION OF FEEDINGS

The regimen for initiating EN primarily depends on the site of feeding and condition of the patient's GI tract. Use of full-strength (i.e., undiluted) formula is recommended for initiation of feedings.[34–37] Dilution delays delivery of adequate nutrients without significantly affecting the incidence of GI intolerance. Hypertonic formulas are diluted rapidly in the GI tract, reaching isotonicity before or shortly beyond the ligament of Treitz (distal end of duodenum). Continuous feedings are commonly initiated at a rate of 10 to 50 mL/hour with advancement by 10 to 25 mL/hour every 4 to 24 hours as tolerated, although stable patients may tolerate initiation of EN at goal rate.[3,34,35] For critically ill patients, those with abnormal GI function, patients without use of the GI tract for a prolonged time, those at risk of refeeding syndrome, and when calorically dense or high-osmolality formulas are used, starting at the lower rate and advancing slowly (i.e., start at 10–20 mL/hour and advance by 10–15 mL/hour every 12 or 24 hours) may be preferable, although this is based on consensus rather than evidence from well-designed studies.[25,33–36]

Patients are typically started on continuous infusion feedings, then transition to intermittent infusions, and eventually to bolus feedings, if desired. Bolus feedings are administered for about 15 minutes to avoid bloating, cramping, nausea, and diarrhea. A rate of less than 60 mL/minute is suggested to minimize GI intolerance with bolus feedings.[36,37] For intermittent feeding, rates of 200 to 300 mL every 4 to 6 hours are generally tolerated; volumes up to 750 mL may be tolerated.[33,36,37] Initiation of feedings at goal rate may be tolerated by some patients, although starting slower is appropriate for most patients.

D.S. receives gastric feeds; therefore, continuous infusion, intermittent infusion, or bolus feedings could all be used. Continuous infusion most commonly is used for hospitalized patients despite no clearly established difference in tolerance compared with intermittent infusion. Full-strength formula should be used to initiate feedings. The goal volume of enteral nutrition for D.S. is 1,440 mL/day of a standard caloric density formula (1.06 kcal/mL,

---

0.44 g protein/mL, 83.5% free water), or 60 mL/hour continuous infusion. The infusion could be started at 30 mL/hour (half goal rate); however, given D.S.'s risk for refeeding syndrome, it is preferable to start slower. Starting at 15 mL/hour for 12 hours, then increasing by 15 mL/hour every 12 hours would achieve the goal rate of 60 mL/hour within 48 hours. If D.S. experiences diarrhea or abdominal distension, the feeding may be held at 15 mL/hour for 24 hours, then increased by only 10 mL/hour every 12 to 24 hour as tolerated. Extra care is required to ensure he receives an adequate fluid intake until the formula is at goal rate.

Continuous infusion enteral feeding can be administered by gravity drip or by enteral pump. With gravity drip, the infusion rate must be adjusted frequently to maintain a consistent flow rate, and formula flow must be checked regularly to ensure that the flow has not stopped. Gravity infusion has no alarms to alert nurses to kinked tubing or empty delivery containers. Enteral pumps provide a consistent flow rate and alarms for problems with the infusion, but they are more expensive than gravity drips. Pumps often are used for hospitalized patients to help maintain delivery of the prescribed volume of enteral formula. Either gravity drip or an enteral pump could be used for D.S., depending on the hospital's protocol for enteral feeding.

To prevent potentially fatal inadvertent IV infusion of non-IV products, new non-

Luer compatible global design standards for small-bore liquid and gas medical device tubing connectors, including enteral feeding connectors, are being introduced under the "Stay Connected" initiative.[38] The connection between the enteral formula bag and the tubing going into the bag changed in 2012. Transition to the new ENFit connector between the administration tubing and feeding tube itself is expected to be completed by 2016. Oral syringes will not fit the new ENFit connectors; therefore, ENFit compatible syringes are required for medication administration, tube flushes, and bolus feeding via syringe.

TRANSITION FROM CONTINUOUS TO INTERMITTENT/BOLUS FEEDING

CASE 37-2, QUESTION 7: D.S. has received EN for 10 days. He has tolerated his continuous tube feeding without problems and has not required electrolyte replacements for the past 4 days. The plan is to transfer D.S. to a skilled nursing facility (SNF) in the next few days. The SNF requests D.S. be on an intermittent/bolus feeding regimen before transfer to the SNF. How should D.S. be changed from continuous infusion to intermittent or bolus feeding?

Many nursing facilities do not routinely use enteral pumps because of increased cost. Without a pump, delivery of the prescribed volume of formula at a consistent rate may not be reliable and increased nursing time may be required to prevent tube occlusion and ensure adequate volume of formula is delivered. D.S. is currently receiving continuous infusion feedings. The transition to intermittent delivery of formula can be accomplished by various methods. An overlapping regimen of gradually decreasing the continuous infusion rate and increasing the intermittent volume appears to be an economical and efficient method of changing the feeding regimen.[33] For D.S., decrease the continuous rate from 60 mL/hour down to 40 mL/hour and add four intermittent feedings of 120 mL over 60 minutes every 6 hours initially. If tolerated, decrease continuous infusion to 20 mL/hour and increase intermittent feeding to 240 mL. Finally, stop the continuous feeding and increase intermittent feedings to 360 mL, or add a fifth feeding to keep the intermittent volume at 285 to 300 mL. To keep the feeding volume in a more convenient increment of 120 mL (half of an 8-ounce can), D.S. could receive two feedings of 360 mL and three feedings of 240 mL if five daily feedings are needed.

Another transition method is to stop continuous feedings and restart feedings with a regimen for initiating intermittent feedings. Starting volume is typically 60 to 120 mL for the first two or three feedings, and feeding intervals are often every 4 hours. Volume is increased by 60 to 120 mL every 8 to 12 hours, as tolerated, until goal is reached.[35] Feeding intervals can be increased once goal volume is reached. D.S. could start with 120 mL over 60 minutes every 4 hours for two feedings, then advance to 240 mL per feeding. If tolerated, the volume per feeding could increase to

360 mL to allow feedings every 6 hours. Once at the desired number of feedings per day, the infusion time could be decreased based on tolerance. If feeding for 30 minutes is well tolerated, D.S. could be changed to bolus administration for 15 to 20 minutes.

The discharge EN prescription should state clearly the desired caloric density, protein content, fiber content per 1,000 kcal, and formula volume, or the daily calories, protein, fiber, and fluid goals. The brand name may be included, but the SNF may not carry the same brand of formula. Any special considerations for the feeding schedule also should be communicated (e.g., D.S. does not tolerate feeding after 9 PM; raise the head of the bed to 45 degrees for 3 hours after the last daily feeding to avoid regurgitation).

FLUID PROVISION

CASE 37-2, QUESTION 8: How much additional fluid must be included in the feeding regimen to meet D.S.'s estimated daily fluid requirements?

The free-water content of EN must be calculated to determine the volume of additional fluid that must be provided. As noted previously, standard caloric density formulas generally contain 80% to 85% free water. The formula selected for D.S. contains 83.5% free water; therefore, at his goal volume of 1,440 mL/day (six cans), the formula provides approximately 1,200 mL of free water daily. Using 1,860 mL daily (30 mL/kg/day × 62 kg) as D.S.'s fluid requirement (see Case 37-2, Question 5), he will need 660 mL/day in addition to the enteral formula. If D.S. had additional losses from vomiting, diarrhea, or other sources, this volume would be added to the 660 mL to determine total volume in addition to enteral formula. The additional fluid is typically provided with medications and tube irrigation (flushes). Feeding tubes should be irrigated with 30 mL of fluid every 4 hours during continuous feeding, or before and after each intermittent or bolus feeding.[34,35] The tube should be flushed with a minimum of 15 mL of water before and after medication administration through the tube, as well as with 15 mL between each medication.[34–37] Fluid also is required for diluting medications before administration through the tube. The flush volume and/or number of flushes will need to be increased to provide D.S. with adequate fluid because 30 mL every 4 hours plus fluid for medication administration will not provide the 660 mL of fluid needed in addition to his EN. Because D.S. is receiving gastric feedings, hypotonic fluid is of less concern than in the jejunum.[39] Increasing flush volumes to between 100 and 150 mL should meet D.S.'s daily fluid requirement, depending on the amount needed for medication administration. Diluting the formula itself to increase fluid provision is not recommended because this increases the risk of error and contamination.

NUTRITION IN CRITICAL ILLNESS

Nutrition support is an important component of care in critical illness where patients are typically in a catabolic stress state and

---

metabolism may be altered. Multiorgan dysfunction, as well as fluid and electrolyte imbalances, adds to the complexity of this population and confounds attempts to provide proper nutrition. The preferred route for nutrition support is generally EN, although the ideal formula composition remains unresolved. Guidelines are periodically updated. The most recently published guidelines should be consulted to determine current recommendations, especially regarding specialized components discussed in this section.

CASE 37-3

QUESTION 1: J.B., a 68-year-old man with a past medical history of hypertension, presents to the ED with complaints of shortness of breath, productive cough, wheezing, and fever. J.B. subsequently requires intubation and is transferred to the ICU with a diagnosis of pneumonia. During the next 24 hours, his respiratory status further declines, and he is diagnosed with acute respiratory distress syndrome (ARDS). In anticipation of a prolonged course of mechanical ventilation, a feeding tube is placed into the small bowel. The chart indicates a height of 70 inches and an admission weight of 75 kg.

Laboratory evaluation today includes the following:
Sodium, 140 mEq/L
Potassium, 3.9 mEq/L
Chloride, 109 mEq/L
Carbon dioxide content, 22 mM
BUN, 18 mg/dL
SCr, 0.8 mg/dL
Glucose, 118 mg/dL
Albumin, 3.6 g/dL
Aspartate aminotransferase, 32 international units/L
Alanine aminotransferase, 37 international units/L
Alkaline phosphatase, 64 international units/L
Total bilirubin, 0.7 mg/dL

Should a specialized critical care formula be used for initiation of EN in J.B.?

J.B. is critically ill and several types of EN formulas have been developed for critically ill patients. However, the role of specialized EN formulas, and certain components in particular, remains controversial in critical illness. Table 37-4 shows a few formulas marketed for critical illness and lists the components which are altered compared to standard polymeric formulas. Due to the catabolic nature of critical illness, formulas are generally high protein, many with an NPC:N ratio less than 100:1 (i.e., high or very high protein content). Other formulas containing slightly lower-protein content (i.e., NPC:N ratio between 100:1 and 125:1) target the inflammatory element of critical illness with addition of components designed to mitigate the inflammatory response. Formulas designed for critical illness are typically fiber-free, although a few formulas include small amounts of soluble fiber. Supplementation of specific amino acids, including branched-chain amino acids (BCAAs), glutamine, and arginine, in EN for critical illness remains an unsettled issue.

Enhanced Branched-Chain Amino Acid Content

Standard EN formulas contain 15% to 20% of protein as BCAAs; enhanced BCAA formulas for critical care contain over 35%, and hepatic failure formulas contain 45% to 50%. High-BCAA stress/critical care formulas are not therapeutically interchangeable with hepatic formulas due to the lower-than-normal concentrations of aromatic amino acids (AAAs), especially phenylalanine, in hepatic formulas.

Guidelines from SCCM–ASPEN recommend a standard enteral formula for patients with acute or chronic liver disease in the ICU.[4] High–very high protein is currently emphasized over BCAA content for critically ill patients.

Glutamine

The proposed role of glutamine in critical illness is enhanced neutrophil function and maintenance of intestinal barrier function, thereby preventing translocation of bacteria and endotoxins from the GI tract into systemic circulation and reducing bacteremia.[40] Glutamine is considered a nonessential amino acid, as it is synthesized in sufficient quantities for its roles in transamination, as an intermediate in numerous metabolic pathways, such as gluconeogenesis and renal ammoniagenesis, as a fuel source for rapidly dividing lymphocytes and enterocytes, and in the synthesis of glutathione. However, during periods of metabolic stress, endogenous synthesis may become inadequate.

Study results are conflicting regarding effects of glutamine supplementation in the critically ill population. Past studies have indicated numerous clinical benefits from glutamine supplementation; however, two recent studies (REDOXs, METAPLEX) suggest increased mortality in critically ill patients receiving parenteral and/or enteral glutamine.[41–44] The CCP guidelines now recommend against the use of enteral glutamine in critically ill patients.[19] Glutamine supplementation should also be avoided in patients with total bilirubin greater than 10 mg/dL or creatinine clearance less than 30 mL/minute because ammonia excretion could be impared.[45] Monitoring for potential complications is essential when glutamine supplementation is used.

Protein-bound glutamine is present in all enteral formulas. Free glutamine is unstable in ready-to-use formulas and, due to poor stability, is not commercially available in an intravenous form. However, glutamine is available as a modular supplement, which can be administered separately from the EN formula. Glutamate is stable in water and functions in many roles attributed to glutamine. Additional research is needed to determine whether physiologic effects are equivalent for glutamate, protein-bound glutamine, and free glutamine.

Arginine

Arginine is a nonessential amino acid synthesized by the urea cycle during detoxification of ammonia and is normally available in sufficient quantities for growth and tissue repair. In times of metabolic stress, however, endogenous synthesis may become inadequate, making arginine conditionally essential. The postulated benefit of arginine in critical illness is related to enhanced protein synthesis, cellular growth, and immune system support. In contrast, several mechanisms have been proposed that suggest potential adverse effects with arginine supplementation, including one in which arginine is used as a substrate in the synthesis of nitric oxide (NO), a potent vasodilating agent, which may also have implications in mitochondria damage, organ dysfunction, and increased gut barrier permeability.[46] Although synthesis of NO increases during sepsis (thereby creating a negative arginine balance), the exact role of this effector molecule remains controversial. Many believe that excess NO is part of an adaptive response directed toward limiting infection, ischemia, coagulation, inflammation, and tissue injury.

Conflicting study results leave considerable uncertainty regarding use of arginine supplemented EN in critically ill patients.[4,18–20],[47] Guidelines, consensus statements, and recommendations have been developed to help the clinician provide evidence-based nutrition therapy; however, many barriers to implementation exist.[4,18–20],[48,49] Use of arginine-containing, immune-enhancing diets is not recommended for critically ill patients in the CCP guidelines because higher-quality studies indicated no effect on mortality with these formulas and increased mortality was reported for septic patients in some studies.[18–20]

Table 37-4

Selected High-Protein Enteral Formulas with Altered Protein or Fat Sources

		Free	Protein					Fat g/L		

Formula[a],[b],[c]	kcal/mL (mOsm/kg)	Water (%)	g/L (% kcal)	NPC:N	Protein Source	ARG g/L[d]	GLN g/L[d]	(% kcal)	Fat Sources
Crucial[c]	1.5 (490)	77	94 (25)	67:1	Hydrolyzed casein; L-arginine	15	–	67.6 (39)	MCT oil; fish oil (<2%); soybean oil; lecithin
f.a.a[c]	1.0 (850)	85	50 (20)	100:1	Crystalline amino acids	–	–	11.2 (10)	Soybean oil; MCT
Impact with Fiber[c]	1.0 (375)	87	56 (22)	71:1	Sodium and calcium caseinates; L-arginine	12.5	–	28 (25)	Palm kernel oil; menhaden oil
Impact 1.5[c]	1.5 (550)	78	84 (22)	71:1	Sodium and calcium caseinates; L-arginine	18.7	–	69 (40)	MCT; palm kernel oil; menhaden oil
Impact Glutamine[c]	1.3 (630)	81	78 (24)	62:1	Whey protein hydrolysate; free amino acids; sodium caseinates; L-arginine	16.3	15	43 (30)	Palm kernel oil; menhaden oil
Optimental[b]	1.0 (540)	83.2	51 (20.5)	97:1	Soy protein hydrolysate; partially hydrolyzed sodium caseinate; L-arginine	5.5	–	28.4 (25)	Structured lipid (interesterified sardine oil [EPA, DHA] and MCT); canola oil; soy oil
Osmolite 1.2 Cal[b]	1.2 (360)	82	55.5 (18.5)	110:1	Sodium and calcium caseinate	–	–	39 (29)	High-oleic safflower oil; canola oil; MCT oil; lecithin
Oxepa[b]	1.5 (535)	78.5	62.5 (16.7)	125:1	Sodium and calcium caseinates	–	–	93.8 (55)	Canola oil; MCT oil; sardine oil; borage oil
Peptamen AF[c]	1.2 (390)	81	75.6 (21)	76:1	Hydrolyzed whey protein	–	–	54.8 (39)	MCT oil; soybean oil (<2%); fish oil (<2%); lecithin
Pivot 1.5 Cal[b]	1.5 (595)	75.9	93.8 (25)	75:1	Partially hydrolyzed sodium caseinate; whey protein	13	6.5	50.8 (30)	Structured lipid (interesterified sardine oil [EPA, DHA] and MCT);

[d]None or unknown indicated by "–."

AF, advanced formula; ARG, arginine; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; FOS, fructooligosaccharides; GLN, glutamine; MCT, medium-chain triglycerides; NPC:N, nonprotein calorie to nitrogen; ω-3FA, ω-3 fatty acids; ω-6FA, ω-6 fatty acids.

IMMUNE-MODULATING FORMULAS

Formulas included in Table 37-4 have an NPC:N ratio less than or equal to 125:1 and also contain supplemental arginine, glutamine, or nucleic acids, or a modified fat component. Such formulas are often referred to as "immune-modulating" formulas based on their proposed beneficial modulation of biologic responses to stress. Study formulas frequently contain varying portions of two or more potentially immune-modifying components, making it difficult to determine the effect of any given component. The subset of immune-modulating formulas intended for patients with acute respiratory distress syndrome (ARDS) and acute lung injury (ALI) is distinct from other formulas and is discussed in more detail under pulmonary disease.

The results of clinical trials examining the effects of immune-modulating enteral formulations on mortality, hospital length of stay (LOS), ICU days, incidence of nosocomial infection, duration of mechanical ventilation, and GI complications are conflicting.[4,18–20,40–47] Several meta-analyses have shown benefit on clinical outcomes (e.g., infectious complications, ventilator days, LOS); however, no mortality benefit has ever been found in critically ill patients receiving immunonutrition versus standard EN.[4,18–20,48]

The population which appears to have better outcomes with immune-modulating EN is patients undergoing major elective surgery, particularly surgery for upper GI malignancy. Reduced infection risk and shorter LOS in high-risk elective surgery patients, mostly patients with upper GI malignancy, receiving immunonutrition with EN supplemented with both arginine and fish oil was shown in a meta-analysis.[47] Joint guidelines from SCCM–ASPEN gave the highest recommendation for use of an immune-modulating EN formula in patients undergoing major elective surgery, trauma, burns, and head and neck cancer; the recommendation was slightly lower for critically ill, mechanically ventilated, nonsurgical medical ICU patients.[4] Conversely, CCP guidelines advise against use of formulas with "arginine and other nutrients" in critically ill patients based on failure to show an infectious or mortality benefit and potential for harm in septic patients.[18–20] Neither the CCP guidelines nor the SCC-ASPEN guidelines recommend use of an arginine-supplemented immune-modulating formula for patients with severe sepsis.[4,18–20] Additional studies with well-defined patient populations are necessary to determine the effects of combinations of immune-modulating components (arginine, glutamine, nucleic acids, ω-3FAs), optimal component and dose combinations, and the most beneficial timing for administration of immune-modulating components.

Altered Fat Components

Stress or critical care and immune-modulating formulas contain different sources of fat to alter the type of fatty acids provided. Fat sources commonly include MCTs, along with predominantly canola oil, high-oleic oils, or fish oils. Absorption of MCTs is relatively independent of pancreatic enzymes and bile salts, and is carnitine-independent; thus, they can be absorbed in patients experiencing malabsorption of the long-chain triglycerides. Formulas containing a relatively large percentage of fat calories as MCTs are frequently marketed for critically ill patients with malabsorption.

Canola oil and high-oleic oils have high monounsaturated fatty acid (MUFA) content. MUFAs have been popularized by reports of low cardiovascular disease in populations using olive oil, but further research is needed to determine the role of these fatty acids in ill patients. Usual polyunsaturated vegetable oils (i.e., corn, soy, and safflower oils) are avoided or provided in relatively small quantities in critical care formulas to limit omega-6 fatty acids (ω-6FAs), which are precursors to inflammatory, vasoconstrictive, and platelet-aggregating agents.[50,51] Some ω-6FAs may, however, be converted to γ-linolenic acid (GLA), then to dihomo-GLA, and subsequently to arachidonic acid.[52] Dihomo-GLA competes with arachidonic acid in the pathways for prostaglandin synthesis resulting "1" series prostaglandins with lower proinflammatory effects, similar to "3" series prostaglandins from ω-3FA. Small amounts of ω-6FAs are required in the diet to prevent deficiency of linoleic acid, an essential fatty acid not provided by MCT and fish oils.

Fish oils, including menhaden oil, provide fatty acids primarily from the ω-3 family, with the very long-chain fatty acids eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) predominating. The proposed role of ω-3FAs in critical illness is to reduce infectious complications and death in selected patient populations. The ω-3FAs are precursors to less inflammatory and more vasodilatory eicosanoids than those from ω-6FA.[50–52]

Few data are available evaluating effects of only fat modification in EN for critical illness, and combinations of immune-modulating components may produce different effects than single nutrients. Improved clinical outcomes for postsurgical and critically ill patients have been associated with EN-containing ω-3FAs, usually in conjunction with other immune-modulating components, although the effects remain controversial.[4,18,26] Some studies suggest data are inadequate to support routine use of fish oil, whereas others indicate the potential for arginine to counteract the benefit of fish oil in EN containing combinations of immune-modulating components.[53,54]

Studies suggest a minimum of 5 to 7 days of supplementation with immune-modulating components, including ω-3FAs, is necessary to see beneficial effects on postoperative outcomes.[49–51] Incorporation of ω-3FAs into cell membranes may be required to see benefits; this has been demonstrated in humans with supplementation for 5 days.[55] Fat modification to provide high-ω-3FA content also has been studied in ARDS and acute lung injury (as discussed in the Pulmonary Disease section).

The question of whether to initiate EN in J.B. with an immune-modulating formula does not have a clear-cut answer. The data provided for J.B. do not indicate sepsis; thus, he would be a candidate for an immune-modulating formula using the SCCM–ASPEN guidelines.[4] The more conservative CCP guidelines would not recommend an arginine-containing immune-modulating formula.[18–20] The decision of whether to use the immune-modulating formula would likely depend on practices within the hospital and the immune-modulating formulas available. Because J.B. was admitted with pneumonia and now has ARDS, the other consideration would be whether a specialized pulmonary formula would be more appropriate for his EN.

PULMONARY DISEASE

CASE 37-3, QUESTION 2: How do pulmonary formulas differ from standard polymeric formulas? If J.B. receives a specialized pulmonary formula, what nutrient modifications should the formula contain?

There are two types of EN formulas intended for patients with pulmonary conditions. Both have a moderate caloric density (1.5 kcal/mL) and the percentage of calories from fat is relatively high (40%–55%), although the types of fats differ. The premise

---

for higher fat content is that fat metabolism produces less carbon dioxide (CO_2) than carbohydrate metabolism, thereby reducing the work load of the lungs. Early studies comparing isocaloric, high-fat, low-carbohydrate diets with higher-carbohydrate diets showed improved respiratory parameters in ambulatory patients with chronic obstructive pulmonary disease (COPD) as well as reduced time on the ventilator and decreased arterial CO_2 concentrations in mechanically ventilated patients.[26,56,57] Caloric intake in these studies ranged from 1.7 to 2.25 times the measured energy expenditure, which is excessive by current standards. Excess calories contribute to higher CO_2 production; thus, the early studies are of questionable relevance, and in practice, preventing overfeeding is as important for control of CO_2 as high-fat, low-carbohydrate diets.[26,27] In addition, improved respiratory parameters with a high-fat EN product are unlikely in patients without excess CO_2 production or retention. Data from 60 malnourished, underweight patients with COPD do suggest respiratory status in this population is more likely to benefit from a high-fat, low-carbohydrate (28% of calories) formula compared with a high-carbohydrate (60%–70% of calories) formula.[58] Although the percent of calories from fat (55%) in the high-fat formula was similar to traditional pulmonary formulas, fat distribution was considerably different with 20% of fat as MCTs and a predominance of MUFAs. Currently marketed pulmonary formulas contain 20% to 40% of fat calories as MCTs and fat sources providing higher MUFAs. During a period of overfeeding for weight gain, pulmonary formulas may be reasonable; however, they are not warranted for routine use in most patients.

The second type of pulmonary EN formula is an immune-modulating pulmonary (IMP) formula with an anti-inflammatory lipid profile (fish oils rich in ω-3FAs, borage oil rich in GLAs), antioxidants (vitamins C and E, βcarotene), and no supplemental glutamine or arginine, which has been studied in patients with ARDS and ALI.[4,18–20] Three studies comparing this formula with a typical high-fat pulmonary formula with elevated ω-6FA content were included in a meta-analysis by Pontes-Arruda et al.[59] and showed a significant reduction in new organ failures, time receiving mechanical ventilation, ICU LOS, and mortality.

Based on the one study available when the initial CCP guidelines were published, the committee recommended use of IMP formulas with a combination of fish oils, borage oil, and antioxidants in patients with ARDS.[18] The SCCM–ASPEN and updated 2009 CCP guidelines evaluated additional studies and both recommended patients with ARDS or ALI be placed on an IMP formula.[4,20] However, the choice of control formula in these otherwise high-quality studies has been questioned because there is some evidence of harmful effects from administration of ω-6FA-rich fats in critically ill patients.[18]

The study by Grau-Carmona et al.[60] compared an IMP formula to standard EN rather than a high-fat pulmonary formula. In 132 septic patients with ARDS or ALI, no difference was found in gas exchange, ventilator days, or infection rate, although ICU LOS was less with the IMP. Based on inclusion of this study and one other with those available from previous CCP evaluations, the 2013 CCP guidelines downgraded their recommendation to consider use of a IMP formula in patients with ARDS or ALI.[20] An additional study using an IMP formula preemptively in severe trauma patients was included in the 2015 CCP guidelines.[19] No difference was found in the level of oxygenation, development of ALI or ARDS, ventilator days, ICU LOS or mortality; however, more patients in the study group developed bacteremia.[61] The

2015 CCP guidelines remained the same as in 2013.[19]

J.B. was diagnosed with ARDS; therefore, an IMP formula could be considered based on the CCP and SCCM–ASPEN guidelines.[4,19,20] The formula should contain fish oils to provide a high-ω-3FA content, borage oil to provide GLA, and increased antioxidant vitamin content. Delayed gastric emptying is associated with high-fat diets and must be considered when evaluating possible benefits and adverse effects of high-fat EN. This applies to both IMP and routine pulmonary formulas. Abdominal distension, increased gastric residuals, nausea, and vomiting can result from delayed gastric emptying. J.B. has his feeding tube placed in the small bowel, so delayed gastric emptying is not a concern. However, the potential to overwhelm pancreatic lipase activity resulting in fat malabsorption should be considered when a high-fat load, especially long-chain triglycerides, is delivered into the small bowel. Continuous infusion is more likely to be tolerated than other, more rapid delivery methods in most patients. As shown in Table 37-2, the cost of routine pulmonary formulas is slightly higher than for standard polymeric formulas and IMP formulas are significantly more expensive.

RENAL FAILURE

CASE 37-3, QUESTION 3: J.B. has been in the ICU for 10 days. His ARDS has improved; however, he now has acute kidney injury and hemodialysis will start today. Morning laboratory results include the following:

Sodium, 131 mEq/L
Potassium, 5.7 mEq/L
BUN, 80 mg/dL
SCr, 3.8 mg/dL
Glucose, 100 mg/dL on an insulin drip
Magnesium, 2.9 mg/dL
Phosphorus, 5.6 mg/dL
WBC, 9.7 × $10^3/\mu L$
Hgb, 11.4 g/dL
Hct, 34.3%

An EN formula for renal failure is ordered. How do the nutrient components in renal formulas differ from standard polymeric EN formulas? Is a renal formula appropriate for J.B.?

Two types of EN formulas for renal disease/injury are available and both are calorically dense (1.8–2 kcal/mL) to limit fluid provision. Highly specialized formulas with enriched essential amino acid content are based on the theory that recycling of urea nitrogen for nonessential amino acid synthesis reduces the accumulation of BUN.[26,56,57] Clinically significant recycling of nitrogen and incorporation into nonessential amino acids does not appear to occur, however. Essential amino acid formulas may be appropriate for patients with chronic renal failure with glomerular filtration rates less than 25 mL/minute/1.73 m^2 who are receiving very low-protein diets and for whom dialysis is not an option.[56] Use should be limited to no more than 2 to 3 weeks, because hyperammonemia and metabolic encephalopathy have been associated with longer use. These formulas are not appropriate for patients with acute kidney injury, such as J.B., or for those receiving dialysis. The NPC:N ratio is approximately 300:1 in these formulas. Water-soluble vitamins are typically included in currently available high essential amino acid formulas; however, vitamin content should be reviewed as some essential amino acid formulas do not contain vitamins. Renalcal contains higher-than-normal essential amino acids with about two-thirds essential combined with one-third nonessential amino acids.

Polymeric enteral formulas designed for renal failure or renal insufficiency are the standard for hospitalized patients with impaired renal function. These formulas contain a balanced amino acid profile and are not enriched with essential amino acids. The NPC:N ratio varies from about 130:1 (for patients with increased nitrogen losses from dialysis) to 230:1 (typically used for nondialyzed patients).

Lower-than-normal concentrations of potassium, phosphorus, and magnesium are used in these formulas to minimize electrolyte problems. Many critically ill patients receiving dialysis for acute kidney injury tolerate a nonrenal formula; however, those with elevated potassium, phosphorus, or magnesium generally require a renal formula to control electrolyte levels. Based on his electrolytes, J.B. will require a renal formula. A polymeric formula with a lower NPC:N ration (i.e., 140:1; moderate protein content) would be appropriate given the plan for dialysis. Polymeric renal formulas meet 100% of the DRI with less than 2,000 mL/day.

Modular Components

CASE 37-3, QUESTION 4: After several days on the renal formula (NPC:N ratio, 140:1), there are indications that J.B.'s protein intake should be higher. Serum electrolytes today include the following:

Sodium, 137 mEq/L
Potassium, 5.1 mEq/L
Phosphorus, 4.5 mg/dL
Magnesium, 2.6 mg/dL
What are the options for increasing protein provision?

J.B. is receiving a renal formula with moderately high-protein content based on the NPC:N ratio of 140:1. There are no very high protein formulas with low potassium, phosphorus, and magnesium on the market; therefore, a very high protein formula will provide significantly more of these electrolytes than J.B. currently receives. His current serum levels of the renally eliminated electrolytes are near the upper end of normal and would likely rise above the normal range if the EN is changed to a nonrenal formula. Using a lower potassium concentration in the dialysis bath might keep serum potassium within normal range. Addition of a phosphate binder to the medication regimen could be considered; however, the risk of tube occlusion may be increased with a phosphate binder. A better option is to provide additional protein from a modular protein component, although this can also increase the risk of tube occlusion if not administered properly.

Modular components are individual nutrient substrates, or combinations of two substrates, designed for addition to oral diets or enteral formula regimens. They provide only the macronutrient(s) without electrolytes or vitamins, and should only be used to supplement a diet or EN, not as a sole source of nutrition. Protein modules are powders containing 3 to 5 g protein/tablespoon. Most protein modules are intact protein. Arginine and glutamine are available as individual packets to allow supplementation as a single amino acid. Glucose polymers are used to supplement calories as carbohydrate. They do not increase osmolality or alter food or formula flavor. Powdered carbohydrate modules contain 20 to 30 kcal/tablespoon, whereas liquids contain 2 kcal/mL. Protein and carbohydrate modular components typically are mixed with water and administered through the feeding tube rather than being mixed directly into the formula. Additional fat can be provided as 50% safflower oil emulsion (Microlipid) or as MCT oil. A combination carbohydrate and fat modular product is available if both sources of calories are appropriate. A modular fiber product containing soluble fiber in the form of partially hydrolyzed guar gum is also available.

Glucose Control Formulas

CASE 37-4

QUESTION 1: M.P., a 59-year-old man, is admitted to the hospital secondary to dehydration and for a GI workup related to a 35-pound unintentional weight loss during the past 3 months. He states he has been unable to eat for a week due to continual nausea, although he reports no vomiting. M.P. received IV fluids in the ED and currently has 0.9% sodium chloride infusing at 125 mL/hour. Past medical history includes hypertension, hyperlipidemia, gastric reflux, and diabetes mellitus type 2. M.P. is 5 feet 11 inches tall and his admit weight is 130 kg. Laboratory values from this morning show the following results:

Glucose, 230 mg/dL
BUN, 20 mg/dL, down from 31 mg/dL in the ED
SCr, 1.2 mg/dL, down from 2.3 mg/dL in the ED
Sodium, 141 mEq/L
Potassium, 4.3 mEq/L
Chloride, 105 mEq/L

His small bowel follow-through study indicates severely delayed gastric emptying. A feeding tube is to be placed into the small bowel for a trial of enteral feeding.

Should a “glucose control” or “diabetic” formula be used for initiating tube feedings in M.P.? How do formulas for glucose control differ from standard polymeric EN formulas?

No ideal macronutrient distribution has been identified for meals intended for patients with diabetes mellitus and general dietary guidelines for healthy eating are considered appropriate.[62] However, formulas for hyperglycemic patients, known as diabetic formulas, do not necessarily follow this recommendation. Diabetic formulas have caloric distributions of 31% to 40% carbohydrate, 42% to 49% fat, and 16% to 20% protein. The carbohydrate content is lower, and fat content is higher than in most standard polymeric formulas. High MUFA sources predominate to provide greater than 60% of fat as MUFAs. The source and type of carbohydrates in diabetic formulas varies, with a predominance of more complex carbohydrates (i.e., oligosaccharides, cornstarch, fiber) and insulin-independent sugars (i.e., fructose). Fiber sources associated with improved glycemic control, mainly soluble fibers but also soy polysaccharide, are included in these formulas to help minimize postprandial hyperglycemia. Fiber content ranges from 14 to 21 g/L and formulas are 1 kcal/mL; thus, the recommended fiber intake of 25 to 38 g daily generally can be achieved with less than 2,000 kcal/day.[29]

Multiple studies comparing diabetic formulas to standard EN formulas providing equal calories and protein have been conducted. Results of a large meta-analysis including 23 studies, 19 being randomized controlled trials, favor the diabetic formulas for glucose control.[63] Postprandial increases in glucose, glucose area under the curve, and peak blood glucose concentrations were significantly reduced with the diabetic formulas. However, there were no significant effects on total cholesterol, high-density lipoprotein, or triglyceride concentrations, or on overall complication rates. Also, mortality differences were not found in the single 2-week trial reporting mortality for critically ill patients. Ability to utilize results of this meta-analysis in practice is limited by many studies of low methodologic quality, inclusion of single-meal trials, and use of oral supplements in healthy volunteers. For hospitalized patients with hyperglycemia, no well-designed clinical trials of adequate size were found to make a recommendation regarding use of diabetic formulas in the ASPEN guidelines regarding adults with hyperglycemia.[64]

M.P. could receive either a diabetic formula or a standard formula. The meta-analysis discussed previously would suggest glucose control may be better with a diabetic formula; however, the ASPEN guidelines found inadequate data to make a recommendation regarding use of diabetic formulas in hospitalized patients with hyperglycemia and the Academy of Nutrition and

---

Dietetics suggests following a general pattern of healthy eating for patients with diabetes.[62–64] Either a diabetic or standard formula would be acceptable for M.P. based on available data. Problems with delayed gastric emptying or fat malabsorption must be weighed against possible benefits of improved glucose control with diabetic formulas. These problems are of minimal concern for M.P. as he is being fed into the small bowel and his history does not suggest fat malabsorption. Treatment goals for EN in patients with diabetes mellitus should include individualization of macronutrient composition, avoidance of excess calories, and maintenance of euglycemia.[62–64] M.P. may benefit from a treatment plan that includes gradual weight loss and this may influence the decision of whether to use a diabetic formula or a very high protein formula that would permit lower total calories while still providing adequate protein.

MONITORING ENTERAL NUTRITION SUPPORT

CASE 37-4, QUESTION 2: What types of complications can occur with tube feeding? What steps can be taken to prevent complications in M.P., and how should he be monitored for complications?

Appropriate monitoring of patients receiving EN is essential to recognize and prevent complications. Complications can be divided into three groups: mechanical, metabolic, and GI (Table 37-5).

Mechanical Complications

The major mechanical complications are tube occlusion and aspiration. Mechanical complications often can be avoided with good nursing technique and careful observation of feeding tolerance. Adequate tube flushing is essential to prevent tube occlusion. Flushing with 30 mL of water every 4 hours during continuous feeding or before and after intermittent feedings is recommended.[34,35] Flushing must also occur before and after medication administration and after withdrawal of gastric contents. M.P.'s tube should be flushed using these guidelines. Frequent assessment of tube placement by auscultation, location of markings on the tube, and withdrawal of gastric contents is important to prevent pulmonary aspiration of the formula secondary to displacement of the tube into the esophagus or pharynx. Tube placement should be evaluated every 4 to 6 hours with continuous feeding, or before each intermittent or bolus feeding.[34,36,37,39,57]

Withdrawal of gastric contents through a gastric tube using a syringe allows evaluation of volume in the stomach (gastric residual volume [GRV]). Endogenous secretions from saliva and gastric fluids, about 4,500 mL/day in normal adults receiving food, contribute to GRV when gastric emptying is impaired. Variations in GRV also occur based on the volume and timing of previous feeds, especially for intermittent or bolus feeds, feeding tube characteristics, and patient position and activity.[36,37] Gastrostomy tubes may yield less volume than NG tubes because of their more anterior position in the stomach. Soft, small-bore feeding tubes may collapse when GRV is checked, resulting in falsely low GRV. GRV is not usually checked through tubes placed in the postpyloric region because (a) problems with tube collapse have been reported and (b) the small bowel does not serve as a reservoir for residuals. M.P. has a jejunal feeding tube; thus, GRV is not reliable when checked through his feeding tube. If M.P. has an NG tube in addition to a small bowel feeding tube, GRV can be checked through the NG tube to assess whether formula is "backing-up" or refluxing into the stomach. Previously, methylene blue or blue food coloring was added to the formula to evaluate reflux; however, reports of mortality associated with this practice resulted in its abandonment.[4,14,34,35] The use of glucose oxidase test strips to detect the presence of enteral formula in tracheobronchial secretions lacks sensitivity and specificity, and the results have not been shown to correlate with aspiration; thus, it is not a recommended practice.[33,34,35,36] Current practice recommendations vary on the GRV volume for to holding feeding; CCP guidelines recommend holding at somewhere from 250 to 500 mL whereas SCCM–ASPEN recommendation holds for GRV greater than 500 mL and consider jejunal placement of the feeding tube when GRV is consistently greater than 500 mL.[4,19,20,35] In addition, use of a promotility agent, preferably metoclopramide, should be considered when GRV is greater than 250 mL after a second check.[19,20] These agents may improve feeding tolerance and formula delivery, and the risk of aspiration may be decreased, although the benefit of these agents has been questioned. If the feeding is held because of a high GRV, hourly evaluation of the GRV is recommended until the volume is less than 200 to 250 mL and the feeding is restarted. The fluid withdrawn for GRV assessment may be infused through the tube back into the stomach to minimize electrolyte imbalances; however, CCP guidelines suggest either discarding GRV or feeding back up to 250 mL may be acceptable.[19,20] Elevating the head of the bed to 30 to 45 degrees, with 45 degrees preferred in critically ill patients, during and after feedings also is recommended to reduce the risk of aspiration.[19,35,39]

Metabolic Complications

Major metabolic complications of EN include hyperglycemia, electrolyte abnormalities, and fluid imbalance. Although rigorous studies evaluating monitoring frequency are lacking, regular biochemical determinations similar to those used for PN are recommended to identify and correct metabolic abnormalities before severe abnormalities occur. Baseline values for serum glucose, SCr, BUN, and electrolytes should be available to guide selection of the enteral formula. The few baseline laboratory results available for M.P. may be adequate as a baseline, but additional laboratory parameters will be necessary as part of the monitoring regimen once EN starts.

Capillary glucose measurements every 6 hours or an insulin protocol is recommended before EN starts in diabetic or hyperglycemic patients or if hyperglycemia is anticipated. Given M.P.'s history of diabetes and a baseline glucose greater than 200 mg/dL, diligent monitoring and treatment of his hyperglycemia is warranted even before EN starts. M.P. will require long-term glucose monitoring; however, routine glucose monitoring in nondiabetic patients can be stopped once a stable euglycemic state is established with EN at the goal volume and infusion regimen.

A basic metabolic panel ([BMP]; serum glucose, sodium, potassium, chloride, bicarbonate, calcium, BUN, and SCr) is generally checked daily after feeding starts in critically ill patients and those at risk of electrolyte abnormalities or renal dysfunction. More stable patients may have serum glucose and electrolytes (sodium, potassium, chloride, bicarbonate) monitored rather than a BMP. During the first week of EN, whether initiated in the hospital or alternate site (SNF or at home), a BMP, phosphorus, and magnesium should be monitored a minimum of 2 to 3 times weekly in patients with weight loss; once or twice weekly may be adequate if there is no weight loss. Monitoring frequency can be reduced once tolerance to tube feeding is established and there are no metabolic abnormalities. Daily BMP for a minimum of 4 to 5 days is probably best for M.P. considering his recent dehydration. Daily phosphorus and magnesium also should be considered for a few days in M.P. because of his significant weight loss and risk of refeeding syndrome (see chapter 38 for a more detailed discussion of refeeding syndrome). Despite being obese, M.P. is at risk of electrolyte abnormalities associated with refeeding syndrome.[25] Failure to monitor M.P. and replace electrolytes as necessary could result in serious electrolyte abnormalities. Once M.P.'s BMP, phosphorus, and magnesium are stable, the frequency of monitoring could be reduced to once or twice weekly. Critically ill patients generally require daily or every other day monitoring while in the ICU. For patients receiving long-term EN, the frequency of laboratory monitoring gradually is decreased. Laboratory monitoring should be done once or twice yearly in stable patients without significant medical problems. Patients who have medical problems that can affect nutrient, electrolyte, or trace element requirements or tolerances should be monitored as appropriate to the medical condition.

Table 37-5

Complications of Tube Feeding

Complication	Cause/Contributing Factor	Treatment/Prevention
Mechanical Complications		
Aspiration	Deflated tracheostomy cuff	Inflate tracheostomy cuff before feeding; keep inflated 1 hour after feeding; consider small-bore feeding tube placed past the ligament of Treitz

	Displaced feeding tube	Reinsert tube, check placement; consider hand restraints or feeding tube bridle
	Reduced gastric emptying	Check residuals every 4–6 hours for gastric tube; raise head of bed 30–45 degrees; use lower-fat formula; use prokinetic medication; use small bowel feeding tube
	Lack of gag reflex; coma	Place feeding tube into jejunum; keep head of bed elevated to 45 degrees; provide continuous feeding
Nasal or pharyngeal irritation or necrosis; esophageal erosion; otitis media	Large-bore, polyvinyl chloride tube for long periods of time	Reposition tube daily, change tape; use smaller-bore tube; position tube to avoid pressure on tissues; moisten mouth and nose several times daily
Tube obstruction	Poorly crushed medications	Crush medications thoroughly, dissolve in water; use liquid medications whenever possible; check compatibility of medication with tube and formula
	Inadequate flushing after medications or thick formula	Flush tube with 50- to 150-mL water after medications or thick formula and every 4–6 hours with 30 mL minimum
	Poorly dissolved or mixed formula	Use blender to mix powdered formula (check manufacturer's mixing guidelines); use ready-to-use formula
	Formula mixed with low-pH substance	Avoid checking gastric residuals when safe to do so; use larger-diameter tubes when checking residuals; avoid administering acidic medications through small-diameter tubes; consider a nonacidic therapeutic alternative; flush with a minimum of 30-mL water before and immediately after medication administration
Gastrointestinal Complications		
Nausea, vomiting, distension, cramping	Too rapid administration	Slow administration rate; change bolus to intermittent infusion
	Osmolarity too high; intolerance to volume of formula	Use isotonic formula; increase the number of bolus or intermittent feedings so the volume per feeding is reduced, or change to continuous infusion; change to a more calorically dense formula if volume is the major problem (osmolarity will likely increase with higher caloric density)
	Gastric retention; poor GI motility	Place feeding tube distal to the pylorus; consider a promotility agent, such as metoclopramide; evaluate medications and change those possibly contributing to gastric dysmotility, if possible
Dumping syndrome (weakness, diaphoresis, palpitations)	Hyperosmolar load bolused or infused rapidly into the small bowel	Do not bolus into the small bowel; temporarily decrease continuous infusion rate and gradually increase rate after symptoms subside; use an isotonic formula
	Rate or volume of feeding increased too fast	Temporarily decrease continuous infusion rate or volume of intermittent or bolus feeding, and gradually increase rate after symptoms subside
Diarrhea	Atrophy of microvilli; malabsorption related to a disease process (e.g., pancreatitis, short bowel syndrome, Crohn disease)	Use a oligomeric formula until absorption improves; use a relatively isotonic and advance slowly; use a formula low in long-chain fatty acids when fat is malabsorbed and/or consider pancreatic enzymes
	Hypertonic formula	Change to a lower-osmolarity formula

	Dumping syndrome	See dumping syndrome entry in this table
	Rapid advancement of formula volume	Temporarily reduce rate or volume, then advance slowly; consider enteral pump for better control of administration rate
	Lactose intolerance	Change to lactose-free formula if previously using lactose-containing formula; evaluate lactose content of medications and supplemental foods, if patient is not strict NPO
	Contaminated formula	Hang fresh formula every 4 to 6 hours when using an open administration system; do not add fresh formula to volume remaining in the feeding container; change the formula container and tubing daily; follow clean/aseptic technique when working with the formula or feeding tube; minimize manipulation of the feeding tube; consider changing to a closed enteral system; avoid powdered formulas requiring reconstitution

Gastrointestinal Complications		
	Medications; antibiotics; magnesium-containing antacid; high-osmolarity liquid dosage forms	Check stool for C. difficile and treat if present; consider probiotic agent; administer antidiarrheal if not contraindicated; consider alternate therapy such as histamine-2 blocking agent or proton pump inhibitor; use calcium-based antacid; reduce dose or divide dose into 3–4/day, when feasible to do so; dilute medication with water before administrations; consider alternate dosage form (transdermal, IV); change to crushed tablet and use appropriate precautions to avoid tube occlusion
Constipation	Inadequate fluid or free-water intake	Increase volume and/or frequency of tube flushes to increase fluid intake; change to a formula with lower caloric density, if possible
	Inadequate fiber intake	Change to a formula with fiber or with a higher-fiber content; administer fruit juice or bulk-forming laxative (e.g., psyllium) using caution to prevent tube occlusion
	Fecal impaction	Administer stool softener daily using caution to prevent tube occlusion if administered via the tube
	Poor gastric/GI motility	Encourage ambulation; consider promotility agent
	Medications, especially narcotics and anticholinergics	Use lowest effective dose of medication and transition to an alternate medication with fewer constipating effects, if possible
Metabolic Complications		
Hyperglycemia, glycosuria (can lead to dehydration, coma, or death)	Stress response; diabetes mellitus	Monitor fingerstick glucose every 6 hours, use sliding scale insulin plus appropriate routine insulin (e.g., insulin drip in critically ill)
	High-carbohydrate formula	Change formula
	Drug therapy (steroids)	Monitor intake and output accurately

Excess CO_2 production (high RQ)	High percentage of carbohydrate calories or excess calories from any source	Reduce total calories to avoid overfeeding; consider formula with higher-fat calories
Hyponatremia	Dilutional (fluid excess, SIADH); inadequate sodium intake; excess GI losses	Use full-strength formula or change to 1.5–2 kcal/mL formula; add salt to tube feeding (1 tsp = 2 g Na = 90 mEq); use diuretics if appropriate; replace GI losses
Hypernatremia	Inadequate free-water intake	Use 1 kcal/mL formula; monitor intake and output accurately; temperature and weight daily; increase flush volume
	Excess water losses (diabetes insipidus, osmotic diuresis from hyperglycemia, fever)	Correct hyperglycemia and the cause of fever or diabetes insipidus
Hypokalemia	Medications (diuretics, antipseudomonal penicillins, amphotericin B)	Monitor serum potassium; give PO or IV potassium replacement PRN
	Intracellular or extracellular shifts (insulin therapy, acidosis)	Correct underlying problem
	Excess GI losses (NG suction, small bowel fistula, diarrhea)	Routinely provide potassium in replacement fluid
Hyperkalemia	Potassium-sparing medications (triamterene, amiloride, spironolactone, ACE inhibitors); potassium-containing medications (penicillin G potassium)	Monitor serum potassium; change to medications without potassium-sparing effect or without potassium salts
	Renal failure	Monitor renal function; change to formula with lower potassium content
Hypercoagulability	Warfarin antagonism due to formula	Hold formula 1–2 hours before and after warfarin dose; monitor coagulation status; check vitamin K content and change to lower vitamin K, if appropriate (most EN formulas are not high in vitamin K)

ACE, angiotensin-converting enzyme; EN, enteral nutrition; GI, gastrointestinal; IV, intravenous; NG, nasogastric; NPO, nothing by mouth; PO, oral; PRN, as needed; RQ, respiratory quotient; SIADH, syndrome of inappropriate antidiuretic hormone secretion.

Weight and fluid status are important parameters to monitor throughout EN therapy, especially in patients with unusual losses, an inability to recognize thirst, or inability to voluntarily adjust their oral fluid intake. For hospitalized patients, weight is primarily a reflection of fluid status and increasing weight for 3 or 4 consecutive days may be an indication fluid intake needs to be reduced, whereas decreasing weight may indicate a need for increased fluid unless the patient had been fluid overloaded. Generally, total fluid can be adjusted by the number of times the feeding tube is flushed daily and the volume of each flush. In long-term patients, fluid is an important parameter for adequacy of caloric intake. Consistent increases or decreases from the required enteral formula volume can have significant effects on weight. For example, a weight loss of 12.5 pounds over the course of a year can be expected if the daily intake of a 1-kcal/mL formula is 120 mL less than required. Changing caloric density of the formula may be a potential option to help manage fluid when altering the number or volume of flushes is not adequate for fluid control. For patients with a stable fluid status, the week-to-week weight change can be used as an indicator of appropriate caloric intake. An upward trend in weight (e.g., ≥3 consecutive weeks with an increase) may indicate a need for fewer calories unless weight gain is a goal. A downward trend may indicate a need to increase caloric intake, unless weight loss is desired. A plan that includes gradual weight loss is appropriate for M.P. based on his obesity.

Respiratory status should be evaluated every 8 hours in hospitalized patients, to help recognize pulmonary edema and pulmonary aspiration. Auscultation with a stethoscope should be conducted at least 2 times per week, but simple observation of the patient's breathing pattern is adequate at other times unless altered respirations are noted. Coughing or respiratory distress may be indications of aspiration or other developing respiratory problems. Vital signs also may provide clues to aspiration or other problems, such as dehydration, fluid overload, or infection.

In addition to monitoring for complications, monitoring for response to EN and changes in nutritional status is recommended. This should occur routinely in patients receiving either short-term or long-term EN. Chapter 35, Basic Nutrition and Patient Assessment, discusses parameters used for nutrition assessment and ongoing monitoring of nutritional status.

Gastrointestinal Complications

Assessment of GI symptoms is important for determining EN tolerance because GI complications are frequently associated with tube feeding. Abdominal distension and bloating should be evaluated at least every 8 hours while M.P. is hospitalized. Abdominal distension may be an indication of accumulating formula. The possibility of falsely low GRV due to malposition or collapse of the tube during withdrawal of gastric fluid should be considered if abdominal distension occurs when GRV is low. Gas formation secondary to lactose intolerance or rapid increases in fiber intake, and poor gastric emptying secondary to a high-fat formula, medications, recent surgery, critical illness, or an underlying disease such as diabetes are among the conditions associated with distension. When considerable distension is present, the formula should be held temporarily, and the patient evaluated further to rule out a contraindication to EN.

Nausea, vomiting, abdominal cramping, diarrhea, and constipation are other GI symptoms monitored as indicators of EN tolerance. M.P. has some of these symptoms associated with his gastroparesis, and disease-associated symptoms should not be confused with feeding intolerance. Vomiting creates the most immediate concern because tube displacement and pulmonary aspiration can occur. Nausea and vomiting commonly occur with a high GRV, severe gastric distension, poor gastric emptying during gastric feeding, GI tract obstruction, or poor GI motility. Diarrhea occurs in 2% to 70% of patients, depending on the definition used, and is one of the most difficult problems for patients and caregivers to address.[34–37] Predisposing illnesses, including diabetes mellitus, GI infections, pancreatic insufficiency, and malabsorption syndromes, are more likely to cause diarrhea in patients receiving EN than the formula itself.[30,33,36] M.P. has type 2 diabetes; however, at this time, diarrhea has not been reported as a problem.

Formula-related GI infections could occur from contamination of an opened can or package. Sources of contamination include the water used for reconstitution or dilution, transfer to the delivery bag, formula kept in the delivery bag for a prolonged period, and poorly cleaned feeding bags or administration sets. Water used to flush the tube can also be a source of contamination; therefore, current practice recommendations are to use sterile water as the flush solution for immunocompromised patients.[35] Closed enteral feeding systems using ready-to-hang bags of formula decrease contamination by reducing manipulation of the bag and formula, and are commonly used in the hospital setting. Concurrent drug therapy (e.g., antibiotics) is another major contributor to diarrhea in tube-fed patients, potentially accounting for 61% of diarrhea cases.[30,36]

Bolus feeding into the jejunum can lead to diarrhea and abdominal cramping, as well as nausea and vomiting. Because M.P. is being fed into the jejunum, he should remain on a continuous infusion protocol. Initiation of EN with a hypertonic formula, a rapid rate of infusion or a large volume, and use of formula at refrigerator temperature are other factors often cited as causing GI symptoms. Although controlled studies have not supported these factors as significant contributors to GI intolerance, subjective evidence suggests they are important. Constipation is most likely to occur with long-term tube feeding in nonambulatory patients. Inadequate fluid intake and lack of fiber may be factors associated with constipation. Diabetic EN formulas contain fiber. However, if the decision is to use a very high protein formula for M.P., a fiber-containing formula would be reasonable to use based on his known history.

MEDICATIONS AND ENTERAL NUTRITION BY TUBE

Patients receiving EN often receive medications through the same tube. Feeding tube occlusion, adverse effects caused by changes in pharmaceutical dosage forms, and alteration of medication pharmacokinetics and pharmacodynamics are among the potential problems.[65–68] Interactions related to pharmacologic or physiologic effects of medications or enteral nutrients also may occur. For this reason, oral medication administration should be considered unless a strict NPO status is required. M.P. has severe gastroparesis, a diagnosis not requiring a strict NPO status; however, the medical

---

team is concerned that medications administered by mouth may have erratic absorption and poor efficacy due to delayed gastric emptying. Medications are ordered to be administered through M.P.'s feeding tube.

CASE 37-4, QUESTION 3: M.P. has been receiving EN for 5 days and has been at goal rate for 2 days. Laboratory evaluation today shows the following:

Sodium, 137 mEq/L
Potassium, 2.8 mEq/L (decreased from 3.7 mEq/L yesterday, 4.1 mEq/L the previous day, and 4.8 mEq/L when tube feeding started)
Chloride, 97 mEq/L
Calcium, 7.8 mg/dL
Magnesium, 1.3 mEq/L (decreased from 2.5 mEq/L 2 days ago)
Phosphorus, 2.5 mg/dL (decreased from 4.7 mg/dL 2 days ago)
Albumin, 2.4 g/dL

Micro-K (8 mEq KCl/capsule) has been ordered as six capsules via feeding tube along with calcium carbonate (260-mg elemental calcium/tablet) as two tablets twice daily via feeding tube. Orders were also placed in the chart for warfarin. He was placed on a heparin drip yesterday for a newly diagnosed deep vein thrombosis (DVT) in his left leg, despite prophylactic heparin therapy since admission. Home medications are to be restarted, including enteric-coated aspirin, 81 mg daily; famotidine tablet, 20 mg twice daily; simvastatin tablet, 20 mg daily; metoprolol succinate tablet, 95 mg daily; and verapamil capsule, 240 mg daily. How should M.P.'s medications be administered when he is receiving EN?

Medication Selection

Solid dosage forms are a challenge to administer by feeding tube. Crushing a medication and mixing the powder in water results in an altered pharmaceutical dosage form, and this may affect its efficacy or patient tolerance. Liquid dosage forms are generally recommended for administration through a feeding tube, but they are not without problems, and a liquid dosage form may not always be the best choice. Liquids should be diluted at a minimum of 1:1 with water before administration to avoid coating the tube interior. High-viscosity liquids, such as suspensions, should be diluted 3:1 with water. Pharmaceutical syrups with a pH of 4 or less must be used with caution because immediate clumping and tackiness of formulas mixed with the syrups have been reported.[65,66] For medications not available in liquid form, a therapeutically equivalent medication in a liquid form can be considered. Extemporaneous preparation of a liquid also may be considered, but can increase cost significantly. Medications in a soft gelatin capsule are best avoided for administration through a feeding tube. If there is no alternative, the capsule can be dissolved in warm water. Undissolved gelatin should not be administered, because this may occlude the tube. The safety and efficacy of simple compressed tablets are not affected by crushing and dissolving in water immediately before use. Simple compressed tablets can be crushed to a fine powder, then dissolved or suspended in water for administration. Powder in hard gelatin capsules can be poured into water and mixed thoroughly before administration through a feeding tube. Failure to adequately suspend or thoroughly dissolve any of these dosage forms in water before administration through the tube can result in occlusion. Some medications appear to be particularly troublesome for administration through a feeding tube. Calcium salts, iron salts, lansoprazole, omeprazole, multivitamins, pentoxifylline, potassium chloride, phenytoin, protein supplements, sucralfate, and zinc salts were identified by nurses as the products most frequently contributing to feeding tube occlusion.[67,68] M.P. has both calcium and potassium ordered today.

Calcium carbonate is a simple compressed tablet that can be crushed, suspended in 30 mL of water, and administered through the feeding tube. Risk of tube occlusion from an inadequately crushed tablet may be decreased by use of calcium carbonate suspension (500-mg calcium/5 mL), if available. Administration of either crushed and suspended tablets or commercial suspension requires flushing the tube with 15 mL of water before and after medication administration.[35] Diluting the suspension at least 1:1 with water, preferably 3:1, and flushing with 75 to 100 mL may be advisable because suspensions may otherwise coat the tube. The appropriateness of calcium supplementation should be questioned, however, because M.P.'s serum calcium concentration is within normal limits after correction for his low serum albumin concentration, and the ionized calcium concentration would likely be within normal limits. Administering any medication via the feeding tube may occlude the tube; therefore, administering an unneeded medication through the feeding tube is an unwarranted risk. For calcium, and for electrolytes in general, only oral and IV dosage forms are available, so the easiest and most cost effective route is an oral dosage form via feeding tube if M.P. cannot take oral medications.

Potassium supplementation is ordered today for M.P.'s low serum potassium. Potassium should have been considered yesterday because the serum level has been decreasing since tube feeding began. The selected potassium supplement is inappropriate for administration by tube because Micro-K is a slow-release product. Crushing any type of slow-release or sustained-release product destroys slow-release mechanisms, resulting in the immediate release of several hours worth of the medication at one time. An exaggerated therapeutic response may be seen initially, followed by a loss of response part way through the dosing interval. Deaths have occurred when sustained-release or long-acting products are crushed before administrations; therefore, these dosage forms should not be crushed.[69] Instead, an immediate-release dosage form should be used, with appropriate adjustment of dose and dosing interval, or an alternate administration route (e.g., intravenous, suppository, transdermal patch) may be available. Potassium chloride powder for solution (three packets with 15 mEq KCl/packet) or liquid (10% KCl 35 mL, 15% KCl 25 mL, or 20% KCl 15–20 mL) should be ordered rather than the slow-release product. Dividing the potassium dose into two or three smaller doses and diluting each dose with 60 mL of water may be better tolerated. Giving 45 to 50 mEq of potassium as a single dose may cause nausea, vomiting, abdominal discomfort, or diarrhea. These symptoms might be mistaken as intolerance to EN, resulting in the tube feeding being stopped temporarily. The larger fluid volume for administration also may help reduce the GI irritation associated with potassium doses.

Potassium supplementation could also be partially accomplished by changing part of the potassium ordered to potassium phosphate, which is available as a 250-mg capsule that provides 8.1 mmol of phosphate and 14.2 mEq of potassium. M.P. appears to have a mild refeeding syndrome, with phosphorus and magnesium slightly less than the normal range and having decreased significantly during the past 2 days.[25] Supplements should be started today so that smaller daily quantities can be used before electrolytes are critically low. This may decrease the risk of diarrhea and GI upset caused by the administration of oral phosphate or magnesium. Contents of each potassium phosphate capsule are designed to be dissolved in 75 mL of water for administration, so dissolution is not a concern. One potassium phosphate capsule twice a day plus KCl liquid to provide 20 mEq potassium is the same potassium dose as is ordered currently. The liquid KCl dose should be separated from the potassium phosphate to minimize GI effects.

Magnesium supplementation could be accomplished with a magnesium oxide tablet (400 or 500 mg) administered 2 to 4 times daily. These are simple compressed tablets that can be crushed and suspended for administration via feeding tube. An alternative would be magnesium hydroxide suspension 5 mL 2 to 4 times daily. Magnesium doses are distributed through the day to reduce the risk of diarrhea. The feeding tube must be flushed adequately before and after each dose of electrolyte replacement. The flush volume should be a minimum of 15 mL, although 75 to 100 mL after the magnesium dose may be better to ensure the electrolyte preparation is out of the tube. The volume of other tube flushes can be adjusted to limit the total fluid intake to the estimated requirements. It can be difficult to provide large quantities of potassium, phosphate, and magnesium via feeding tube secondary to the GI intolerance they cause. Therefore, IV electrolyte replacement may be necessary if intracellular depletion is extensive and M.P. does not tolerate oral electrolyte replacement.

Famotidine is a simple compressed tablet that can be crushed. However, both the verapamil and metoprolol dosage forms ordered for M.P. contain multiple doses intended to be slowly released. The once-daily dosing schedule helps identify these two medications as slow-release products and, for metoprolol, the succinate salt is also a clue as this is different than other dosage forms of metoprolol. Both verapamil and metoprolol should be changed to immediate-release dosage forms if M.P. cannot take them by mouth. The dose and frequency of dosing will need to be adjusted to reflect the immediate release dosage form.

Enteric-coated tablets are designed to release medication in the small bowel because the medication is either acid labile or irritates the stomach. Protection for the medication or stomach is lost when enteric-coated tablets are crushed and delivered via feeding tube into the stomach, resulting in decreased efficacy of the medication or increased gastric irritation. When an irritating medication must be given by tube into the stomach, diluting the medication in at least 60 mL of water is recommended.[65] M.P. has enteric-coated aspirin ordered for administration into a jejunal feeding tube. The enteric coating is designed to dissolve in the small bowel and could be dissolved with bicarbonate solution before administration into the small bowel. However, it would be better to use a noncoated tablet for his aspirin dose. If enteric-coated beads, such as those found in several proton pump inhibitor dosage forms, are to be administered through a feeding tube, use of an acidic liquid (e.g., fruit juice) helps prevent the enteric coating from becoming sticky and adhering to the inside of the feeding tube. This should only be considered for a large-bore feeding tube, such as a gastrostomy, or the beads will occlude the tube. Film-coated tablets also cause problems when crushed because the coating does not crush well and becomes sticky in water. M.P.'s simvastatin has a film coating and may be a problem to crush and administer through the feeding tube.

Administering buccal or sublingual dosage forms via feeding tube may result in altered absorption or destruction of the medication by stomach acid. Therefore, therapeutically equivalent medications (e.g., isosorbide dinitrate rather than sublingual nitroglycerin) or an alternate route of administration (e.g., nitroglycerin ointment or transdermal system rather than sublingual nitroglycerin) should be used. A listing of medications that should not be crushed is available at **http://www.ismp.org/Tools/DoNotCrush.pdf**.[70] Carcinogens, teratogens, or cytotoxic agents that should not be crushed are included in the list.

Pharmacokinetic parameters can be altered when medications are administered by feeding tube. M.P. has a jejunal tube and delivering medication into the jejunum could affect bioavailability, although few studies address this issue. Medications taken orally are delivered to the stomach, where dissolution occurs for most dosage forms and hydrolysis of some medications may occur. Delivery into the small bowel may alter these processes, thereby affecting bioavailability. For instance, recovery of digoxin from intrajejunal dosing is higher than with oral administration, primarily because of reduced intragastric hydrolysis.[28,65] Bioavailability of medications also can be affected by the presence of enteral formula in the GI tract. Medications affected by the presence of food are expected to be affected in a similar manner by the presence of formula.[66,68] For example, administration of tetracycline with formula present is expected to reduce tetracycline bioavailability because of interactions with divalent cations. A similar interaction is expected between ciprofloxacin and enteral formula, although some evidence suggests a mechanism other than binding with divalent cations is responsible for reduced ciprofloxacin concentrations with enteral feeding.[28]

Phenytoin is particularly troublesome to manage in patients receiving EN, with reduced phenytoin concentrations reported in numerous case reports and small studies. Methods suggested for management include using a meat-based formula, administering phenytoin capsules rather than the suspension, and stopping formula delivery for 1 to 2 hours before and after the phenytoin dose.[65,71] Holding formula administration before and after phenytoin dosing is often recommended, although others claim that adequate dilution will reduce loss of the medication. None of these methods, however, clearly prevents low phenytoin concentrations; thus, monitoring of serum concentrations is important whenever EN is started or altered. Large-scale, controlled trials are needed to determine the most appropriate method for managing the phenytoin–EN interaction.

Warfarin can also be troublesome to manage in patients with a feeding tube, and M.P. is to start warfarin for a newly diagnosed DVT. Reversal of warfarin anticoagulation by vitamin K included in enteral formulas is an important pharmacologic interaction.[28] The vitamin K content of most enteral formulas today is about the same as found in a mixed diet and is unlikely to interfere with anticoagulation, but should be evaluated if adequate anticoagulation is difficult to achieve. In addition, binding of warfarin to a component of enteral formulas, likely protein, has been proposed to explain warfarin resistance with formulas containing low vitamin K content; others suggest binding to the feeding tube itself may occur.[28,66] Stopping formula administration for an hour before and after warfarin administration appears to prevent this type of interaction. Unfortunately, rigorous, randomized studies to provide evidenced based guidance for the management of this potential interaction are lacking.

Liquid dosage forms are often hypertonic. Diarrhea is a potential problem related to physiologic effects of hypertonic medications. Diluting hypertonic medications (e.g., potassium chloride) with 30 to 60 mL of water before administration is suggested. Dividing the medication dose and separating doses by about 2 hours also decrease GI effects of hypertonic medications. In addition, selection of brands and dosage forms with minimal sorbitol can reduce the risk of diarrhea. Sorbitol is a nonabsorbed sugar alcohol found in many liquid dosage forms. Cumulative sorbitol doses greater than 5 g can cause bloating and flatulence, whereas larger doses may act as a cathartic.[35,65,66]

Tube Occlusion

CASE 37-4, QUESTION 4: M.P.'s feeding tube has occluded (clogged). What are the causes of feeding tube occlusion and how can occlusions be managed? What can be done to avoid occluding M.P.'s tube in the future?

The incidence of feeding tube occlusion is 1.6% to 66%.[9,34,35,67] Pump malfunction, lack of periodic tube flushing, formula characteristics, and tube characteristics are nonmedication-related

---

factors affecting tube occlusion. Important tube characteristics include the inner diameter (bore size), tube material, and the arrangement and number of delivery holes (ports) at the distal end. The most important formula characteristic appears to be the protein source. In vitro studies suggest formulas with intact protein, particularly caseinates or soy, coagulate and clump when exposed to an acidic pH, whereas formulas with hydrolyzed protein do not.[28,65]

Medication-related factors influencing feeding tube occlusion include the administration method, dosage form, pH, and viscosity. Medications must be crushed to a fine powder, mixed with water to form a smooth slurry, and adequately diluted before administration. Medications admixed with formula have the greatest potential for occluding tubes owing to alteration of the texture, viscosity, or physical form of the medication or formula. Therefore, medications should not be admixed directly with formula. The enteral formula infusion should be stopped, and the tube flushed with a minimum of 15-mL water before and after medication administration and with 15 mL between each medication.[34,35,36,39,65] Contact between medications and formula within the tube lumen should be limited to decrease the risk of occlusion. Each medication should be administered separately to reduce the risk of interactions.

When a feeding tube occludes, it must be replaced unless patency can be restored. Frequent tube replacement disrupts nutrient delivery and increases patient discomfort as well as the cost of care. The initial treatment for tube occlusion is to flush the tube with warm water using a large syringe, at least 20 mL but preferably 50 mL, to avoid generation of excessive pressure that could rupture the tube. When a specific cause for occlusion can be identified (e.g., a specific medication) and physiochemical characteristics of the responsible product are known (e.g., solubility, pH), it may be possible to select a more appropriate flush preparation than water. In most cases, however, use of an acidic or basic flush preparation could worsen the occlusion. Acidic liquids (e.g., cranberry juice, diet soda, regular soda) may perpetuate or extend the occlusion, especially when coagulated proteins are the cause.[65,66] When water fails to restore patency, activated pancreatic enzymes may be effective. Previously, one crushed pancrelipase tablet and one sodium bicarbonate tablet (324 mg) were dissolved in 5 mL of warm water just before instillation into the occluded tube.[36,65] A product containing multiple enzymes, buffers, and antibacterial agents in a powder form (Clog Zapper) is commercially available. Adherence to flush protocols and proper medication administration techniques are essential to maintain patency once tube patency is restored.

Transfer to Home on Enteral Nutrition

CASE 37-5

QUESTION 1: D.S., an 80-year-old man, was admitted 2 days ago from an SNF for evaluation of large bruises on his right arm and shoulder and possible collarbone fracture due to a fall. He receives intermittent feedings through his PEG. The volume is 1,680 mL (seven cans) daily. D.S.'s history indicates he was hospitalized approximately 7 weeks ago with an ischemic stroke and was discharged to an SNF (see Case 37-2). D.S.'s tube-feeding volume has increased from 1,440 mL on discharge, but the formula remains the same (1.06 kcal/mL, 0.044 g protein/mL, 15 g fiber/1,000 kcal polymeric formula). His weight has increased 2 kg since hospital discharge, and his overall status has improved. Bone fracture is ruled out and D.S. is able to participate in physical therapy (PT). The PT consult indicates D.S. can ambulate safely with a walker and is able to transfer from bed to chair and to the bedside commode with minimal assistance. He is deemed appropriate for outpatient PT after hospital discharge. The swallow study performed this morning indicates D.S. must continue NPO for at least another 4 months when the swallow study will be repeated again. D.S.'s daughter has made arrangements for him to move in with her family. She is concerned about insurance coverage for the EN therapy and states D.S. has Medicare insurance, including a Part D prescription plan. Will Medicare cover EN?

Before addressing the coverage of EN therapy in the home, it should be determined whether D.S. is an appropriate candidate for home versus return to the SNF. Based on the PT assessment, it is likely D.S. is appropriate for discharge home, providing he will have some supervision and assistance available. Typically, a case manager or social worker is involved in arranging appropriate discharge facilities; however, the healthcare professional managing nutrition support in the hospital setting should facilitate the nutrition support portion of discharge, as necessary. The pharmacist should review the medication regimen to assure it is appropriate for administration through the feeding tube.

Strict guidelines exist for home EN coverage. Medicare Part B (not Part D) will cover 80% of the cost if criteria are met.[72–74] EN must be medically necessary to "maintain weight and strength commensurate with overall health status" and there must be a functional disability of the GI tract (e.g., dysphagia, swallowing disorder) that is expected to be "permanent." The formula must be delivered by feeding tube (i.e., not oral supplements) and must provide most of the patient's nutritional requirements (i.e., not supplemental nutrition). Approval is on an individual basis, requires a physician's written order, and sufficient documentation must be available to support the need for EN. Calories less than 20 kcal/kg/day or greater than 35 kcal/kg/day require additional documentation. The duration of therapy must be 90 days or more to meet the test of permanence. D.S.'s therapy falls within these guidelines. In addition, the formula D.S. receives is in a category that does not require him to meet additional eligibility criteria related to the formula itself. Additional documentation would be needed to justify a pump if D.S. was receiving EN via pump.

Enteral formulas are divided into five categories for reimbursement purposes by Medicare Part B (Table 37-6). Formula manufacturers typically list the Medicare category on the product label. Most polymeric formulas containing intact (whole) protein and 1 to 1.2 kcal/mL are in category I. These products do not require documentation of medical necessity for the specific formula itself, but still require documentation of the need for EN. Clear documentation of medical need for formulas in specific categories (e.g., categories III and IV) is required for their higher reimbursement rates. Appropriate forms available from the Centers for Medicare and Medicaid must be completed for Medicare reimbursement of any EN therapy.[75]

Evaluation of Tube Feeding Intolerance

CASE 37-6

QUESTION 1: J.N., a 30-year-old man, was admitted to the hospital 70 days ago after a motor vehicle crash. He sustained multiple traumatic injuries and exhibited multiple complications requiring several exploratory laparotomies. He has been treated for multiple infections, including pneumonia, sepsis, and wound infection. Treatment for Clostridium difficile diarrhea was completed 3 weeks ago and he has not had diarrhea since then. Lysis of adhesions, closure of an enterocutaneous fistula, and placement of a feeding jejunostomy tube (J tube) were done during the last laparotomy 9 days ago. Enteral feedings were started through his J tube 4 days ago and advanced to the goal rate of 90 mL/hour within 24 hours. The EN lactose-free and fiber-free, 460 mOsm/kg, contains 15% of calories from a 50% MCT–50% long-chain triglycerides fat mix, and provides 35 kcal/kg/day and 1.6 g protein/kg/day, which is less than his protein goal. The product is ready-to-use in a closed-system bag. J.N. has received PN for nutrition during most of his hospitalization and the PN rate was decreased as EN increased. J.N. now has diarrhea, which started approximately 12 hours after his EN was increased to goal rate. What is the likely cause of diarrhea? What other information related to the EN regimen would be helpful to determine whether the EN should be stopped and the PN formulation restarted?

Diarrhea develops in 12% to 32% of hospitalized patients, and in up to 80% of high-risk patients; a point preference of 12.4% has been reported.[76] In patients receiving EN, 15% to 40% develop diarrhea, which is multifactorial. Factors associated with diarrhea, but not related to EN, include medications, partial small bowel obstruction or fecal impaction, bile salt malabsorption, intestinal atrophy, hypoalbuminemia, malnutrition, infections such as C. difficile, and underlying conditions affecting the GI tract.[4,30,36,37,39,65,66,76–78] The LOS, particularly over 3 weeks, and EN over 11 days have also been associated with developing diarrhea.[77,79] Tube feeding-related causes of diarrhea include high-fat content, lactose content, and bacterial contamination. Formula temperature, caloric density, osmolality, formula strength, lack of fiber content, and method of delivery have been associated with diarrhea, although these factors are not shown to affect diarrhea in some studies, making a cause-and-effect relationship unclear.[78,79]

J.N.’s hospitalization has been unusually long and complicated. Many factors could contribute to diarrhea; however, the diarrhea coincides relatively closely with initiation and advancement of tube feeding. He may have intestinal atrophy and impaired absorptive function because of his prolonged period without GI tract stimulation. He has had multiple surgeries, including GI surgeries, and may have reduced absorptive capacity, bile salt malabsorption, dumping syndrome, or reduced pancreatic enzyme availability related to his complications and surgeries. At least theoretically, an oligomeric formula would be better absorbed if any of these conditions exist. The SCCM–ASPEN guidelines recommend a standard formulation for those not meeting guidelines for an immune-modulating product.[4] The CCP guidelines were downgraded in 2013 from recommending use of a polymeric formula to consider use of a polymeric formula, although clinical outcomes do not appear to differ between the types of formula.[18–20] However, studies have not evaluated patients without use of the GI tract for weeks before EN initiation. Formula selection is often determined by physician preference and the calorie, protein, and fat content of formulas on the institution's formulary. Because J.N. had been more than 2 months without significant use of the GI tract, he was started on an oligomeric formula.

The EN formula selected for J.N. is only slightly more than isotonic. Risk of diarrhea from fat malabsorption should be minimal with the low-fat content and MCT mix. Increasing EN to goal rate within 24 hours may have contributed to diarrhea. Initiation at 10 to 20 mL/hour and advancement by 10 mL every 8 to 12 hours to reach goal in 48 to 72 hours would have been appropriate for J.N. because he had not used his GI tract for over 2 months.[33–37] The jejunum adapts slowly to changes in volume or concentration, and formula volume was increased less than 24 hours before diarrhea started. Also, an enteral infusion pump should be used to maintain consistent flow. Changing to a lower volume should decrease stool output within 24 hours if the volume change was responsible. If J.N. does not respond to decreasing formula volume, the formula may be held for 24 hours to assess whether diarrhea decreases or stops. Diarrhea related directly to EN usually is an osmotic diarrhea that stops within 24 hours of stopping the formula.[39] A more objective approach than stopping the formula is to measure stool osmolality. Enteral-formula-induced diarrhea is associated with a large osmotic gap, whereas secretory diarrhea (e.g., infectious diarrhea) is associated with a low or negative osmotic gap.[39]

Table 37-6

Medicare Categories for Enteral Formulas

Category and Code[a]	Description	Examples (Partial Listing)
Category I B4150	Semisynthetic intact protein or protein isolates (general purpose formulas)	Boost, Isosource HN, Jevity 1.0 Cal, Nutren1.0 Fiber, Osmolite 1.2 Cal
Category II B4152	Intact protein or protein isolates;	Boost Plus, Ensure Plus HN, Isosource 1.5 Cal, Jevity 1.5 Cal, Nutren 2.0, Resource 2.0

	calorically dense	
Category III[b] B4153	Hydrolyzed protein or amino acids	Optimental, Peptamen 1.5, Peptamen AF, Perative, Vital HN
		Documentation that may provide justification for use: dumping syndrome, uncontrolled diarrhea, evidence of malabsorption on appropriate semisynthetic formulas (e.g., isotonic, low long-chain fat content, lactose-free) that resolves with an oligomeric formula or documentation of the disease process causing malabsorption
Category IV[b] B4154	Defined formula for special metabolic need (i.e., disease-specific formulas)	Advera, Alitraq, Glucerna 1.0, Glucerna 1.5, NutriHep, Nepro with Carb Steady, Nutren Renal, Oxepa, Peptamen, Pulmocare, Renalcal, Suplena with Carb Steady
		Documentation that may provide justification for use: evidence of inability to meet nutritional goals with category I or II products without compromising patient safety and documentation of the specific diagnosis for which a formula is intended
Category V[b] B4155	Modular components for protein, fat, and carbohydrate	Protein: Complete amino acid mix, ProMod Liquid Protein Carbohydrate: Moducal, Polycal, Polycose Carbohydrate and Fat: Duocal Fat: MCT oil
		Documentation that may provide justification for use: inability to meet specific nutrient requirements (i.e., protein, carbohydrate, or fat) with a commercially available formula

[a] Code refers to the Health Care Procedure Code System (HCPCS) billing code used by providers billing the Center for Medicare and Medicaid.

[b] Failure to provide adequate documentation of medical necessity for the specific formula will likely result in denial of claim or payment at the lower category I rate for Medicare Part B insurance coverage.

MCT, medium-chain triglyceride.

The selected oligomeric formula is ready-to-use and in a closed-system bag; therefore, bacterial contamination from mixing technique is not of concern. Cleanliness during formula transfer to the delivery bag, the period of time formula is in the bag, and methods of cleaning the delivery bag may contribute to bacterial contamination of formula. J.N. is receiving formula from a closed enteral system (i.e., ready-to-hang formula-filled containers), and this virtually eliminates transfer-related contamination when proper technique is used. Any addition (e.g., medication, carbohydrate, fat or protein module, MCT oil) to the prefilled container before hanging can contaminate the system, and guidelines (e.g., hang-time, set changes) for an open enteral system then apply. Even when administered separately from the formula, modular components are a potential contributor to diarrhea due to their osmolarity and potential contamination during preparation and administration. The selected formula does not meet J.N.'s protein requirement; therefore, a modular protein is needed to supplement the enteral formula. The nutrition plan includes addition of a modular protein component; however, on review of the medication administration record, this has been started.

Medications are a major contributor to diarrhea in tube-fed patients.[30,36,77–79] J.N. currently receives antibiotics and has for some time. However, the prevalence of diarrhea with antibiotic therapy is difficult to determine due to failure to report stool frequency and consistency as well as lack of a clear definition of diarrhea. C. difficile may have relapsed after his previous treatment. Stool specimens should be sent for culture and/or C. difficile toxin. Evaluation of J.N.'s medications may reveal medications associated with diarrhea (e.g., sorbitol-containing products, antacids, oral magnesium, potassium chloride, phosphate supplements, H_2 receptor antagonists) for which therapeutic alternatives or different routes of administration could be considered.[28,36] High-osmolality liquid medications should be diluted before administration to reduce GI side effects.[34,35,65,66]

J.N.'s GI tract should continue to be used to the extent possible. EN appears to be better than PN for maintaining the GI tract barrier and host immunologic function.[4,18–20],[49,55] Both the CCP and SCCM–ASPEN guidelines recommend use of EN over PN in critically ill patients.[4,18–20] Both guidelines also recognize the need for PN at some point when EN cannot meet the patient's nutritional requirements; however, neither guideline addresses patients with long-term, chronic critical illness such as J.N. The risk of sepsis increases without enteral stimulation of the GI tract. Whether this occurs through bacterial translocation, an unproved process in humans in which enteric bacteria or endotoxin crosses the GI mucosa into mesenteric lymph nodes and portal circulation, or through another mechanism is unclear. In addition, the GI tract serves an immune function, especially with respect to IgA secretion. Respiratory tract infections, such as pneumonia, may increase without proper stimulation of the GI tract, owing to less-effective protection from IgA. Compared with PN, EN attenuates catabolism in highly stressed patients, although initiation of feedings soon after the stressing event may be required to obtain this response. Before a decision is made to stop J.N.'s EN, all possible causes of diarrhea should be investigated. Possible benefits of improved fluid and electrolyte balance from stopping EN should be weighed against the potential benefits of reduced infections from continued use of the GI tract. Combined EN plus PN can also be considered, especially if J.N. tolerates partial EN but cannot advance to goal rate. Full PN should be provided if EN is stopped for more than 1 or 2 days.

Adult Parenteral Nutrition

Susan L. Mayhew and Richard S. Nicholas

CORE PRINCIPLES

		CHAPTER CASES
1	Parenteral nutrition (PN) formulations are complex intravenous (IV) admixtures that require strict adherence to safe compounding practices.	**Case 38-2 (Questions 5-8), Case 38-3 (Question 8), Case 38-4 (Question 7), Tables 38-1, 38-2 and 38-4**
2	Parenteral nutrition (PN) is indicated in patients with a nonfunctioning gastrointestinal tract. Patients should be assessed for appropriate indications of the use of PN.	**Case 38-2 (Question 1), Table 38-3**
3	Calories, protein, fluid, electrolytes, vitamins and minerals are based on the patient's individual needs and are determined by baseline nutritional status, medical history, clinical presentation and IV access.	**Case 38-1 (Questions 1-6), Case 38-2 (Question 4), Case 38-3 (Questions 1, 4, 5 and 9), Case 38-4 (Question 1, 2, 4 and 5), Tables 38-6–38-8**
4	Before PN is initiated, the practitioner must be aware of potential metabolic and respiratory complications, including refeeding syndrome, increased carbon dioxide production, and hyperglycemia. Appropriate fluid, macronutrient, and micronutrient adjustments to specialized nutrition support must be implemented to avoid or diminish the expected complications.	**Case 38-2 (Questions 3 and 9), Case 38-3 (Questions 2, 3, and 6, 7), Case 38-4 (Question 3)**
5	Appropriate monitoring of the patient's vital signs, body weight, temperature, serum chemistries, hematologic indices, nutrition intake, and fluid intake and output are essential to determine the success of PN therapy and to make changes in therapy.	**Case 38-2 (Question 9), Case 38-3 (Question 7), Table 38-5**
6	Advancements in the delivery of home PN have increased patients' acceptance and empowered engagement in self-care. An understanding of the patient's fluid and nutrient needs is essential for optimal delivery of home PN, to help ensure positive outcomes and the best quality of life for the patient.	**Case 38-4 (Questions 5 and 6)**
7	Practitioners should be aware of the additional complications associated with home (or long-term) delivery of PN including hepatobiliary complications, metabolic bone disease, and catheter-related complications.	**Case 38-4 (Questions 7–9)**

⑧	Fluid requirements, macronutrient selections, electrolyte quantities, and vitamin and mineral alterations may be warranted in patients presenting with hepatic or renal failure, short bowel syndrome, obesity, diabetes, pancreatitis, and respiratory failure.	**Case 38-1 (Question 2), Case 38-3 (Questions 1-3), Case 38-4 (Questions 3 and 5)**

It has long been established that a patient’s nutritional status directly impacts recovery from illness or injury. Malnutrition is associated with multiple complications including poor wound healing, infection, prolonged hospital stays, and increased mortality.[1] The preferred method of providing nutritional support is through the gastrointestinal (GI) tract. If using the GI tract is not feasible, intravenous feeding is an option. For centuries clinicians attempted intravenous feeding using crude intravenous cannulas and nutritional substances ranging from olive oil to cow’s milk. Unfortunately, historical attempts at using the vascular system for nutritional support were fraught with challenges. Clinicians were limited by the amount of calories administered, lack of reliable intravenous (IV) access, and risk of infection because of a lack of sterility.[2]

The advent of central venous catheters (CVCs) in the 1960s ushered in the contemporary practice of intravenous feeding—parenteral nutrition (PN) therapy. CVCs allow the administration of concentrated nutritional admixtures that are rapidly diluted in the systemic circulation. Prior to the development of central catheters, peripheral catheters were used which limited the amount of calories and nutrients that could be safely administered.[3]

VENOUS ACCESS SITES

PN formulations are administered through peripheral or central veins. The type of venous access utilized primarily depends on the anticipated duration of therapy and nutrient requirements of the patient.[1]

Peripheral Venous Access

Peripheral venous access is generally the route of choice when PN is expected to be utilized for less than 10 days and when energy and protein requirements are low to moderate. Patients requiring peripheral parenteral nutrition (PPN) must have good peripheral venous access and must be able to tolerate large volumes of fluids, because of the low concentrations of dextrose and amino acids used in PPN formulations.[4]

PN formulations are hypertonic and irritating to peripheral veins. In adults, the osmolarity of PPN formulations should be maintained below 900 mOsm/L (normal serum osmolality 280–300 mOsm/L) to minimize vein irritation and patient discomfort. With peripheral venous access, low final concentrations of dextrose (5%–10%) and amino acids (3%–5%) are necessary and frequent venous access site rotation (every 48–72 hours) is required. Several liters of PPN may be needed daily to meet energy and protein needs of the patient because of the dilute nature of the peripheral admixture. Caloric density of peripheral formulations is less than 1 kcal/mL and can be increased by administering intravenous lipids concurrently or by adding lipids to the dextrose and amino acid mixture. Lipids may protect the vein against irritation through dilution and by a buffering effect.[5,6]

Central Venous Access

Central venous access is the preferred route of administration of PN formulations for patients who have a nonfunctional GI tract, require bowel rest for more than 7 days, have limited peripheral venous access, or have energy and protein needs that cannot be met with peripheral nutrient formulations.[1,4,7]

Traditionally, the CVC is percutaneously inserted into the subclavian vein and threaded through the vein so the tip rests in the upper portion of the superior vena cava (SVC) just above the right atrium. A newer catheter technique involves the use of a peripherally inserted central catheter (PICC) that is inserted in the antecubital vein and advanced until the end of the catheter reaches the upper SVC.[7–9] The internal and external jugular veins may also be used to thread a catheter into the SVC; however, maintaining a sterile dressing on these sites is more difficult than with the subclavian or PICC approach. The SVC is an area of rapid blood flow, which quickly dilutes concentrated parenteral nutrient formulations, thereby minimizing phlebitis or thrombosis. Some patients are not candidates for placement of catheters in the SVC and require a femoral vein insertion with the tip of the catheter in the inferior vena cava. There may be a greater risk for infection with catheters placed using this technique.[6,7]

Differing from PPN, parenteral nutrient formulations designed for administration through central veins often contain relatively high concentrations of dextrose (20%–35%) and amino acids (5%–10%), plus lipids. The central PN formulation typically provides a caloric density greater than 1 kcal/mL and an osmolarity greater than 2,000 mOsm/L. Central PN formulations are often termed total PN because complete nutrient needs of the patient may be delivered by this route.

COMPONENTS OF PARENTERAL NUTRIENT

FORMULATIONS

PN formulations are complex mixtures containing up to 40 different nutrient components, including energy substrates such as carbohydrate (dextrose), protein (amino acids), and fat (lipid or IV fat emulsion), along with water, electrolytes, vitamins, and trace minerals. Various combinations of these components are prepared under aseptic conditions based upon individual patient needs.[10,11] The three macronutrients used in PN formulations are available in various concentrations from manufacturers. Sterile water for injection is used to dilute the macronutrients to achieve the prescribed final concentrations of dextrose, amino acids, and lipids, as well as the final volume of the PN formulation.

PN formulations may be prepared in one of two ways, a dextrose–amino acid (2-in-1) mixture in which IV fat emulsion (IVFE) is administered separately as a piggybacked infusion or a total nutrient admixture (TNA or 3-in-1) in which the dextrose, amino acids, and IVFE are combined in solution in the same bag. Premixed PN solutions are also available commercially in different percentages of dextrose and amino acid preparations. Premixed PN solutions are sterile products that have a longer shelf life; however, these formulations limit the ability to customize the final product to meet individual patient needs.

Errors have occurred in preparing and managing this complex therapy, resulting in patient harm and death. A responsibility of the pharmacist is to ensure safe, accurate, and sterile preparation of the PN formulation. Guidelines for safe practices have been developed for situations in which inconsistent practices have the potential to cause harm. Pharmaceutical problem areas that are addressed in the Safe Practices for Parenteral Nutrition Formulations are compounding, formulas, labeling, stability, and filtering of PN formulations.[12]

PN is a costly therapy. Costs associated with PN therapy include not only the admixture but also the expense of obtaining venous access, laboratory monitoring, and treatment of complications of therapy. Because of the cost and complexity of PN therapy, its use should be scrutinized and reserved for patients who will benefit from it.

Carbohydrate

Dextrose in water is the most common carbohydrate for IV use. It is available commercially in concentrations ranging from 2.5% to 70%. Dextrose solutions are mixed with other components of the PN formulation and diluted to various final concentrations with sterile water for injection. Dextrose in its hydrated form provides 3.4 kcal/g, compared with dietary carbohydrate which provides 4 kcal/g.

Another carbohydrate energy substrate is glycerol, a sugar alcohol with a caloric density of 4.3 kcal/g. It is available as a premixed PN formulation (3% glycerol with 3% AAs) for administration as PPN. Because of the dilute concentrations of this premixed formulation, large volumes are generally necessary to meet caloric requirements.

Lipid

Lipid or intravenous fat emulsion (IVFE) is the most calorically dense macronutrient for infusion and a source of essential fatty acids (FA). The optimal composition of IVFE has been a focus of clinical debate because of the potential to influence immune function, inflammatory response, and liver function. This has prompted research into the development of new lipid formulations (structured lipids) in which part of the n-6 polyunsaturated fatty acids (PUFA) has been replaced by less bioactive FAs, such as coconut oil (rich in medium chain saturated FA), olive oil (rich in n-9 monounsaturated FA oleic acid), or fish oil (rich in n-3 polyunsaturated FA)—challenging the traditional soybean oil and soybean/safflower oil emulsions (n-6 FA).[13] While structured IVFEs have been used for years outside of the United States, the US Food and Drug Administration has recently approved an IVFE formulated with a 4:1 combination of olive oil and soybean oil[14] and another IVFE formulation containing soybean oil, medium-chain triglycerides (MCT), olive oil and fish oil.[13,14]

The traditional IVFEs are available commercially as 10% (1.1 kcal/mL), 20% (2.0 kcal/mL), and 30% (3.0 kcal/mL) concentrations. While each gram of fat provides 9 kcal, the caloric density of the IVFE is increased slightly because of the glycerol within the IVFE such that each milliliter of 10% IVFE provides 1.1 kcals, and each milliliter of 20% and 30% IVFE provides 2.0 kcal/mL and 3.0 kcal/mL respectively. Other components of the IVFE include glycerol to make the formulation isotonic, egg phospholipid as an emulsifier, vitamin K, and sodium hydroxide to adjust the final pH. The 10% and 20% IVFEs may be administered concurrently (IV piggyback) with dextrose/amino acid solutions or mixed with dextrose and amino acids within the PN formulation. The 30% IVFE is used exclusively for compounding formulations that combine dextrose, amino acids, and lipid in the same container.[15]

Amino Acids

Synthetic crystalline amino acids serve as the source of protein and nitrogen (6.25 g protein = 1 g nitrogen). Nitrogen is the building block of cell structure and is used to produce enzymes, peptide hormones, as well as structural and serum proteins. When oxidized for energy protein yields 4 kcal/g. Protein calories have not always been included in the calculation of energy needs for patients receiving PN formulations.

Ideally, amino acids are used to stimulate protein synthesis and tissue repair and are not oxidized for energy; however, the human body cannot compartmentalize energy metabolism in such a manner. Today, conventional wisdom is to include protein calories in the total calorie calculations. Table 38-1 summarizes available nutrients and their caloric density.

Amino acid concentrations of 3.5% to 20% are available commercially and vary slightly from one product to another in specific amounts of each amino acid, electrolyte content, and pH. Generally, amino acid (AA) products are characterized as standard mixtures or specialty mixtures. Standard AA products provide a balanced mix of essential, nonessential, and semi-essential amino acids, whereas specialty AA products are modified for specific disease states.

Table 38-1

Caloric Density of Intravenous Nutrients

Nutrient	kcal/g	kcal/mL
Amino acids	4	
Amino acids 5% Amino acids 10%		0.2 0.4
Dextrose	3.4	
Dextrose 10% Dextrose 50%		0.34 1.7
Dextrose 70%		2.38
Fat	10	
Fat emulsion 10% Fat emulsion 20%		1.1 2
Fat emulsion 30%		3
Glycerol	4.3	
Glycerol 3%		0.129
Medium-Chain Triglycerides	8.3	

Specialty AA mixtures are available for neonatal patients and for adult patients with hepatic encephalopathy, renal failure, or critical illness. Specialty AA formulations designed for patients with hepatic failure contain increased amounts of branched-chain amino acids (BCAA) and decreased amounts of aromatic amino acids (AAA) compared to standard AA products. These formulations are thought to counter the imbalance between AAA and BCAA that can occur in hepatic failure. Elevations in AAA may lead to altered mental status. There is no evidence to suggest that formulations enriched with BCAA improve patient outcomes compared with standard formulas.[16–18] Formulas enriched with BCAA should be reserved for patients with hepatic encephalopathy refractory to standard treatment with luminal acting antibiotics and lactulose.[16] Specialty amino acid products used in renal failure are predominantly comprised of essential amino acids.[19] Their use is based upon the theory that nonessential amino acids can be recycled from urea and essential amino acids. Indications for renal amino acid formulations are limited.[20] Standard amino acids should be used in acute kidney injury.

Modified amino acid formulations are also available for critically ill patients with hypercatabolic conditions such as trauma or thermal injury. These formulations contain increased amounts of the BCAAs (leucine, isoleucine, and valine) to address the increased skeletal muscle catabolism that can be seen in severe metabolic stress. While these BCAA enriched products may slightly improve nitrogen balance, improved patient outcomes have not been demonstrated.[21,22] For a summary of the various amino acid formulas, see Table 38-2.

Micronutrients

Micronutrients are electrolytes, vitamins, and trace minerals needed for metabolism. These nutrients are available from various manufacturers as either single entities or in combinations. For example, the trace element zinc is available commercially as a single trace element product or as a combination product with copper, chromium, manganese, and selenium. Likewise, electrolytes are available as individual salts or as a combination product to facilitate admixing. Commercially available vitamins for PN formulations are generally prescribed as a combination multivitamin regimen, although some vitamins are available as single additives. It is important to be aware of the specific products available in each institution to avoid providing inadequate or excessive amounts of various micronutrients.

PARENTERAL NUTRITION

Patient Assessment: Population-Based Formulation

CASE 38-1

QUESTION 1: A.A. is an 70 year-old man brought to the emergency department who is unable to speak, has a left-sided facial palsy, and left-sided muscle weakness in his upper and lower extremities. He is admitted to the hospital with a diagnosis of ischemic stroke. Evaluation of swallowing with modified barium swallow shows A.A. is at increased risk of aspiration. Enteral tube feedings are started to prevent aspiration. A.A. develops abdominal pain and bloating while receiving enteral feedings. Other enteral formulas and regimens are tried with the same results. Enteral feedings are stopped at this time and a short-term peripheral PN formulation is to be started. His weight today is 186 lbs; his height is 70 inches.

Nutrition laboratory panel values are as follows:

Sodium (Na), 142 mEq/L
Potassium (K), 4.1 mEq/L
Chloride (Cl), 100 mEq/L
Bicarbonate (HCO_3^-), 25 mEq/L
Blood urea nitrogen (BUN), 10 mg/dL
Creatinine, 1.0 mg/dL
Glucose, 91 mg/dL
Calcium (Ca), 9.4 mg/dL
Magnesium (Mg), 2.1 mg/dL
Phosphorus (P), 3.4 mg/dL
Total protein, 6.0 g/dL
Albumin, 3.6 g/dL
Prealbumin, 18 mg/dL
White blood cell (WBC) count, 8,800/µL
Assess his nutrition status.

A.A. is a well-developed, well-nourished man prior to admission. However, A.A.'s visceral proteins are in low-normal range, indicating he may be at increased risk for malnutrition. See Chapter 35, Basics of Nutrition and Patient Assessment, for a more detailed description of evaluation of patients with nutritional deficiencies. The principles from Chapter 35 will be applied to this and all others cases throughout this chapter. He has a minimal stress level and his baseline electrolytes are within normal limits.

CASE 38-1, QUESTION 2: Calculate calorie and protein goals for A.A. using population estimations.

A.A.'s initial calorie goals are to meet his current energy expenditure needed for basal metabolism and account for mild stress associated with stroke recovery. A.A. would fall into the category of "hospitalized patient, mild stress" requiring 20 to 25 kcal/kg/day (see Table 35-3 in Chapter 35, Basics of Nutrition and Patient Assessment). For this calculation, A.A.'s actual weight of 186 lbs (84.5 kg) should be used because his metabolism and current energy expenditure have caused a decrease in body mass. Using usual weight or ideal body weight in patients who have severe weight loss may result in overfeeding. For A.A., the caloric goal should be 1,690 to 2,113 kcal/day.

Protein goals are estimated based on weight, degree of stress, and disease state. Because A.A. has had a stroke and his metabolic stress is mild his protein goal should be based on the desire to maintain his current protein status. Using the guidelines provided in Table 35-4 (Chapter 35, Basics of Nutrition and Patient Assessment), A.A.'s protein dose is 1.0 g/kg/day (range 1.0–1.2), or 85 g/day. As with energy expenditure, calculations of protein needs are only estimates; the patient's clinical course should be monitored and the protein dose adjusted accordingly. The protein source for PN is synthetic amino acids. Generally, 1 g of protein is equivalent to 1 g of amino acids. A.A. will need 85 to 101 g/day of amino acids.

In patients with chronic kidney disease, protein intake should be adjusted according to catabolic rate, renal function, and possible protein losses from dialysis.[23–25] Patients with compromised renal function may require protein restriction to delay the progression of renal disease. Protein intake for patients receiving continuous renal replacement therapy should range between 1.8 and 2.5 g/kg/day.[23–25] Patients with acute kidney injury who receive hemodialysis may demonstrate positive nitrogen balance with protein dose of 1.5 g/kg/day.[26] The recommended protein intake for patients who receive maintenance hemodialysis is 1.2 g/kg/day,[27,28] while patients who receive chronic ambulatory peritoneal dialysis should receive 1.3 g/kg/day.[29]

Table 38-2

Amino Acid Product Comparison

Description	Product Name	Available Concentrations (%)
Standard Formulations		
Contain essential[a] and nonessential[b] amino acids, some available with electrolytes[c]	Aminosyn, Aminosyn II FreAmine III Novamine ProSol Travasol	3.5,[c] 5, 7,[c] 8.5,[c] 10,[c] 15 3, 8.5, 10 15 20 3.5,[c] 5.5,[c] 8.5,[c] 10
Hepatic Failure Formulations		
Contain essential and nonessential amino acids with a proportion of branched-chain amino acids (leucine, isoleucine, valine)	HepatAmine HepAtasol	8 8
Renal Failure Formulations		
Contain primarily essential amino acids; RenAmin also contains a complement of nonessential amino acids	Aminess Aminosyn-RF NephrAmine RenAmin	5.2 5.2 5.4 6.5
Stress Formulations		
Contain percentages of leucine, isoleucine, and valine, as well as all essential and nonessential amino acids	Aminosyn HBC FreAmine HBC	7 6.9
Supplements		
Contain only branched-chain amino acids (isoleucine, leucine, valine); must be used with a general formulation	BranchAmin	4

[a] Essential amino acids: isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, valine, histidine.

[b] Nonessential amino acids: cysteine, arginine, alanine, proline, glycine, glutamine, aspartate, serine, tyrosine.

[c] These concentrations are available with or without electrolytes.

New York, NY: McGraw-Hill; 1994:891.

CASE 38-1, QUESTION 3: A.A. has a peripheral IV catheter, and his peripheral access appears to be adequate. Is he a candidate for using a peripheral PPN formulation?

With good peripheral access, A.A. meets one of the criteria for PPN. Furthermore, he should be able to tolerate the volume of a PPN formulation necessary to meet his goals. A common complication (up to 70%) of PPN is thrombophlebitis, which generally occurs within 72 hours.[5,30] Phlebitis is usually attributed to the acidic pH or hyperosmolarity of the PN formulation. The osmolarity of typical peripheral parenteral feedings ranges from 600 to 900 mOsm/L compared with an osmolarity of 280 to 300 mOsm/L of plasma. Osmolarity of a dextrose–amino acid formulation can be approximated quickly by multiplying the percent dextrose concentration by 50 and the percent amino acid concentration by 100. Approximately 150 to 200 mOsm/L should be added to account for the contribution of electrolytes, vitamins, and trace elements. Although the concurrent administration of fat emulsions decreases osmolarity, buffers the pH, and improves peripheral vein tolerance, it does not eliminate the risk of thrombophlebitis.[31] If PN is anticipated to be a long-term therapy for A.A., central venous access should be obtained.

CASE 38-1, QUESTION 4: Design a parenteral nutrient base formulation and determine the amounts of each macronutrient stock solution needed to compound the PN formula for A.A. based on the caloric and protein goals determined previously.

A.A.'s caloric and protein goals are determined to be approximately 1,900 kcal/day and 85 g protein/day. Giving 85 g of protein per day will provide 340 kcal/day (1 g protein = 4 kcal). Subtracting these protein calories from total desired calories results in the amount of nonprotein calories needed (to be provided by carbohydrates and fat). For A.A., this would be 1,900 total calories minus 340 protein calories, or 1,560 nonprotein calories needed. Typically, dextrose should account for 60% to 70% of nonprotein calories, and lipids would account for the remaining 30% to 40% of nonprotein calories. Providing A.A. with 1,092 kcal of dextrose (approximately 321 g of dextrose; 1 g dextrose = 3.4 kcal) will supply 70% of nonprotein calories as dextrose. The remaining 30% of nonprotein calories will be provided by lipids at 468 kcal (46.8 g of lipids; 1 g of IV lipids = 10 kcal).

For dextrose, a 70% stock solution provides 70 g of dextrose/100 mL. To obtain 321 g of dextrose, 459 mL of the stock solution is needed:

$$\begin{aligned}\text{Dextrose Volume mL} &= 321\text{ g dextrose} \times 100\text{ mL}/70\text{ g dextrose}\\ &= 459\text{ mL}\end{aligned} \qquad \text{(Eq. 38-1)}$$

Similarly, the volume necessary to provide 85 g of amino acids with a 10% stock AA solution is 850 mL. IV lipids at 20% provide 2 kcal/mL or 20 g/100 mL. Using this stock solution, 234 mL would provide 46.8 g of lipids. The total volume of the dextrose, AA, and fat solution would be 1,543 mL/day. Additional volume will be required as electrolytes, vitamins, trace elements, and water are included in the final formulation.

CASE 38-1, QUESTION 5: The institution administers PPN using a 3-in-1 system at 100 mL/hr (2,400 mL/day). This PPN regimen will meet the majority of nutrient goals. Will this meet A.A.'s maintenance fluid requirements?

Maintenance fluid needs can be estimated using several methods. The simplest method uses 30 to 35 mL/kg/day as the basis. Another method is to provide 1,500 mL for the first 20 kg body weight plus an additional 20 mL/kg for actual weight beyond the initial 20 kg. Both methods provide estimates of fluid needs for basic maintenance, and additional fluid must be provided for increased losses such as vomiting, nasogastric (NG) tube output, diarrhea, or large open wounds. A.A.'s fluid needs are estimated as follows:

$$\begin{aligned} \text{mL/day} &= 1{,}500\text{ mL} + ([20\text{ mL/kg}][84.5\text{ kg} - 20\text{ kg}]) \\ &= 1{,}500\text{ mL} + (20\text{ mL/kg})\,(54.5\text{ kg}) \\ &= 1{,}500\text{ mL} + 1090\text{ mL} = 2{,}590\text{ mL} \qquad \text{(Eq. 38-2)} \end{aligned}$$

The PPN formulation is slightly less than A.A.'s needs of 2,590 mL/day. The PPN can be increased to 2,600 mL/day to better meet fluid needs. This will also slightly increase his calorie and protein intake bringing him closer to his goal requirements. Another option would be to provide any additional fluids via a separate IV line. It is important to not supply fluids in excess. The extra fluid intake may put patients at risk for becoming fluid overloaded. Therefore, A.A. should be monitored for signs of fluid overload, including peripheral edema, shortness of breath, daily intake exceeding daily output, hyponatremia, and rapidly increasing weight.

CASE 38-1, QUESTION 6: What are the benefits of using a mixed-fuel system, combining dextrose and fat to meet energy needs?

Providing a portion of calories as fat may reduce the metabolic consequences of excessive dextrose administration. The maximal rate of dextrose metabolism in adults is 5 to 7 mg/kg/minute, or approximately 7 g/kg/day. In doses greater than 7 g/kg/day, dextrose is used inefficiently and converted to fat.[32] The conversion to fat may be associated with respiratory compromise and hepatic dysfunction.[33–35] Hyperglycemia, another complication of excessive dextrose infusion, is associated with electrolyte and acid–base disturbances, osmotic diuresis, increased risk of infections, and altered phagocyte and complement function. Furthermore, using a mixed-fuel system allows the administration of a small amount of IVFE daily and avoids the need for larger boluses of lipid twice weekly to prevent essential fatty acid deficiency (EFAD). Rapid administration of IVFE has been associated with alterations in the reticuloendothelial system that are not observed with continuous administration of small doses.[36] IVFE should be infused at a rate of less than 0.11 g/kg/hour to prevent adverse effects, which include impaired hepatic, pulmonary, immune, and platelet function.[11] Administration of essential fatty acids as 1% to 4% of total caloric intake (e.g., 250 mL of 20% lipid twice a week) is necessary to prevent EFAD.

The essential fatty acids, linoleic acid and α-linolenic acid, are those that cannot be synthesized by humans. Of these, linoleic acid appears to be the only one required by adults. Clinical symptoms of EFAD are dry, thickened, scaly skin, hair loss, poor wound healing, and thrombocytopenia, which may be observed after a few weeks to months of lipid-free parenteral feedings.[29] Biochemical evidence of EFAD, determined by a triene to tetraene ratio of greater than 0.4, may be seen after 1 week of lipid-free parenteral feedings. The continuous infusion of hypertonic dextrose from the PN is associated with high circulating concentrations of insulin. Because insulin promotes lipogenesis rather than lipolysis, linoleic acid cannot be released from adipose tissue.[34]

Patient Assessment: Moderate Stress

CASE 38-2

QUESTION 1: B.B. is a 64-year-old woman who was diagnosed with ovarian cancer 4 years ago. The cancer was treated with a combination of chemotherapy and external beam radiation therapy. B.B. subsequently developed chronic radiation enteritis. She is admitted to the hospital for a complaint of increasing abdominal pain with eating for 7 days, and no stool output for 5 days. Questioning reveals that over the past week she has been drinking only liquids secondary to nausea and vomiting, and her weight has decreased 6 lbs during that time. Review of systems is positive for abdominal pain. On physical examination, B.B. appears thin, and her abdomen is distended. Vital signs are notable for a temperature of 38.5°C, heart rate of 88 beats/minute, and a blood pressure of 102/68 mm/Hg. She is 5 feet 6 inches tall and weighs 110 lbs (50 kg). Her medical record indicates that 1 month ago she weighed 116 lbs (52.7 kg), and 6 months ago her weight was 122 lbs (55.4 kg).

Admission laboratory values are as follows:

Na, 133 mEq/L
K, 4.5 mEq/L
Cl, 100 mEq/L
HCO_3^-, 25 mEq/L

Evaluation of B.B. with an abdominal CT scan shows bowel obstruction with a stricture distal to the obstruction and signs of chronic inflammation. B.B. is admitted with complications from chronic radiation enteritis. Why is B.B. a candidate for PN?

PN should be considered when the patient's nutrient intake has been inadequate for 7 days or longer and the GI tract is not functioning. B.B. has eaten little in the past week, and her 5% decrease in weight is a concern. Furthermore, her weight has decreased by more than 10% during the past 6 months, which is considered a severe weight loss. B.B. is not expected to resume oral intake because her radiation enteritis is being managed conservatively with bowel rest.

Assessment of weight loss should include evaluation of hydration status, especially because B.B.'s vomiting and minimal oral intake for the past week place her at risk of dehydration. Loss of lean body mass is probably less than that reflected by the decrease in weight. In addition, B.B.'s admission serum albumin concentration is low at 3.1 g/dL. Her hydration status should be considered when evaluating this visceral protein, since B.B.'s serum albumin concentration will probably decrease further after she is rehydrated. Because B.B.'s GI tract is not functioning, PN is indicated. For a list of the most common primary diagnoses for the use of PN in hospitalized patients, see Table 38-3.

CASE 38-2, QUESTION 2: What type of malnutrition does B.B. have?

B.B. exhibits some loss of fat and muscle, as well as depletion of visceral proteins. She has components of both marasmus and kwashiorkor malnutrition; therefore, she would be considered to have mixed protein-calorie malnutrition (see Chapter 35, Basics of Nutrition and Patient Assessment).

Table 38-3

Most Common Primary Diagnoses for TPN in Adult Hospitalized Patients

Top 10 Primary Diagnoses TPN
Intestinal or peritoneal adhesions with obstruction
Acute pancreatitis
Septicemia
Diverticulitis
Acute respiratory failure

Intestinal obstruction
Aspiration pneumonitis
Gastrointestinal complication
Coronary atherosclerosis
Pneumonia

CASE 38-2, QUESTION 3: Members of the medical team are anxious to have B.B. gain weight and are concerned by her malnourished appearance. What potential complications could result from aggressively feeding B.B.?

B.B. may be at risk of refeeding syndrome. Chronic malnutrition may lead to intracellular depletion of phosphorus, potassium, and magnesium that may not be evident when measuring serum electrolyte concentrations. Refeeding syndrome may occur as phosphorus, potassium, and magnesium shift from the extracellular space into the cells upon consumption of concentrated sources of calories. Carbohydrate calories are converted to glucose which triggers the secretion of insulin, which in turn, facilitates the uptake of glucose, water, phosphorus, and other intracellular electrolytes. This phenomenon was first reported in World War II when chronically malnourished survivors were given normal food and liquid diets. Complications coinciding with refeeding these individuals included hypertension, cardiac insufficiency, seizures, coma, and death. These complications were reported later in the 1970s and 1980s, with the introduction of PN in chronically ill, essentially starved hospitalized patients. Knowing a patient's history of weight loss and diet will help to assess the risk of refeeding syndrome. Specialized nutrition support should be initiated and advanced slowly for "at risk" patients, along with close monitoring to avoid serious electrolyte abnormalities and the cardiovascular consequences thereof.

To minimize the risk of refeeding syndrome in B.B., all electrolyte abnormalities must be corrected before nutrition support is initiated. Because B.B.'s electrolytes are within normal range, no baseline adjustments are necessary. Nutrition should then be implemented slowly and vitamins administered routinely. Laboratory values including phosphorus, potassium, magnesium, and glucose should be monitored at least daily for the first week.[38,39]

Overfeeding should be avoided in all patients, especially those with respiratory concerns (i.e., mechanically ventilated, chronic obstructive airway disease). Overfeeding with carbohydrates is particularly detrimental because of the amount of carbon dioxide produced relative to the amount of oxygen consumed. This results in carbon dioxide retention that may lead to alterations in acid–base balance. Complete oxidation of carbohydrate is demonstrated at dextrose infusions of 4 to 5 mg/kg/minute (20–25 kcal/kg/day). Infusions exceeding this rate increase carbon dioxide production

---

and may cause respiratory distress. In designing a PN formulation for B.B., it is important to provide a moderate calorie dose and to limit her dextrose dose to less than 4 mg/kg/minute.[40,41] For adults, the daily lipid intake should not exceed 2.5 g/kg/day. However, current literature supports a maximum of 1 g/kg/day. It is also important to monitor serum triglyceride levels to assess tolerance to this dose of IVFE. If the blood sample is obtained while the triglycerides are infusing, as with the TNA formulation, a serum triglyceride concentration of 400 mg/dL, although elevated, is acceptable.[42] Hypertriglyceridemia can sometimes be noted quickly by gross observation of turbidity in the blood sample.

CASE 38-2, QUESTION 4: After hydration with IV fluids, B.B.'s weight is 51.5 kg. PN therapy was delayed because within 24 hours after admission, B.B. experienced severe abdominal pain and distension and required surgery. An exploratory laparotomy was performed, and 25 cm of ileum was resected to remove an area of bowel with severe disease and a stricture that was causing the obstruction. Bowel sounds are absent. She has a right Port-A-Cath CVC and PN is to begin on postoperative day 1. Calculate energy and protein goals for B.B.

Energy requirements may be estimated with predictive equations, simplistic formulas (25–30 kcal/kg/day) or measured by indirect calorimetry, the most accurate method. Over 200 predictive equations have been published in the literature, including the Harris–Benedict equation. Using the Harris–Benedict equation for women (see Table 35-3 in Chapter 35, Basics of Nutrition and Patient Assessment) and her current weight of 51.5 kg, height of 167.6 cm, and age of 64 years, B.B.'s basal energy expenditure (BEE) is 1,158 kcal/day. To estimate her total energy expenditure, the BEE should be modified with an activity factor of 1.2 for being confined to bed and a stress factor of 1.2 for surgery. These modifications result in an estimated energy expenditure of 44% greater than her BEE, or 1,668 kcal/day. Therefore, an energy goal of 1,600 kcal/day is reasonable. In a similar manner, her protein goal (see Table 35-4 in Chapter 35, Basics of Nutrition and Patient Assessment) for moderate stress is 62 to 77 g/day of protein (1.2–1.5 g/kg/day).

CASE 38-2, QUESTION 5: Design a TNA parenteral nutrient formulation as a single daily PN bag for B.B. that provides 1,600 kcal and 70 g of amino acids with a non-protein calorie distribution of 75% carbohydrate and 25% lipid. The macronutrients available on the formulary for compounding the parenteral nutrient formulations are 70% dextrose, 30% lipid emulsion, and 10% amino acids.

1. Amino acids calculation

$$\begin{aligned} \text{Calories from amino acids (protein)} &= 70\ \text{g} \times 4.0\ \text{kcal/g} \\ &= 280\ \text{kcal} \\ \text{mL of 10\% amino acids} &= 70\ \text{g}/0.1\ \text{g/mL} \\ &= 700\ \text{mL} \qquad \text{(Eq. 38-3)} \end{aligned}$$

2. Dextrose calculation

$$\begin{aligned}\text{Calories from dextrose} &= (1{,}600 - 280)\,(0.75)\\ &= 990\ \text{kcal}\\ \text{g of dextrose} &= 990\ \text{kcal}/3.4\ \text{kcal}/\text{g}\\ &= 291\ \text{g}/\text{mL of }70\%\text{ dextrose}\\ &= 291\ \text{g}/0.7\ \text{g}/\text{mL}\\ &= 416\ \text{mL}\end{aligned} \tag{Eq. 38-4}$$

3. Lipid emulsion calculation

$$\begin{aligned}\text{Calories from lipid} &= (1{,}600 - 280)\,(0.25)\text{ or}\\ &\quad\ (1{,}320 - 990)\\ &= 330\ \text{kcal}/\text{mL of }30\%\text{ lipid emulsion}\\ &= 330\ \text{kcal}/3.0\ \text{kcal}/\text{mL}\\ &= 110\ \text{mL}\end{aligned} \tag{Eq. 38-5}$$

4. Calculation of final volume of energy substrates

$$\begin{aligned}&700\ \text{mL amino acids }10\% +\\ &416\ \text{mL dextrose }70\% + 110\ \text{mL lipid emulsion }30\%\\ &= 1{,}226\ \text{mL total volume}\end{aligned} \tag{Eq. 38-6}$$

B.B.'s goal PN formulation will provide 291 g of dextrose and approximately 33 g of lipids daily. If the PN is infused continuously over 24 hours, B.B. will receive 3.9 mg/kg/minute of dextrose and 0.6 g/kg/day of lipids. Both dextrose and lipid doses comply with the limitations recommended in question 3. Other additives such as electrolytes, vitamins, and trace elements are included in the parenteral nutrient formulation and slightly increase the final volume to 1,680 mL/day. The infusion rate for this formulation can be calculated as follows:

$$\begin{aligned}\text{Hourly infusion rate (mL/hour)} &= 1{,}680\ \text{mL}/\text{day}\\ &\quad\ 24\ \text{hours}/\text{day}\\ &= 70\ \text{mL}/\text{hr}\end{aligned} \tag{Eq. 38-7}$$

B.B.'s parenteral nutrient formulation of 1,680 mL/day will not meet her maintenance fluid needs of 2,130 mL/day (see Case 38-1, Question 5). She will require extra fluid to meet the remainder of her basic fluid needs. These additional fluids should be provided through another IV or added as sterile water to the TNA solution.

CASE 38-2, QUESTION 6: What are the advantages and disadvantages of combining the dextrose, fat, and amino acids in one container?

PN formulations may be prepared in one of two ways: a dextrose–amino acid (2-in-1) mixture in which IVFE is administered separately as a piggybacked infusion or a total nutrient admixture (TNA or 3-in-1) in which the dextrose, amino acids, and IVFE are combined in solution in the same bag.[43]

While the use of TNAs have been widely embraced by home care providers and many institutions for convenience and cost advantages, the addition of IVFE to the traditional mixture of dextrose and amino acids converts the mixture into a complex emulsion with physiologic differences that alter the stability of the product.[44] The differences between these two methods of compounding PN formulations must be considered. Specific advantages and disadvantages of each are summarized in Table 38-4.

CASE 38-2, QUESTION 7: How stable are the TNA parenteral feeding formulations compared to 2-in-1 formulations? Why is an infusion filter necessary?

IVFE gradually deteriorates over time because of increased formation of free fatty acids and a resultant decrease in pH. When lipids are mixed with dextrose and amino acids, this process is accelerated. IVFE consists of an interior oil phase dispersed within an external water phase. Stability of the IVFE is maintained by polar and nonpolar regions on the same fat droplet. The surface of the polar region of the fat droplet is negatively charged and repels other lipid droplets of the same charge. When the surface loses its negativity, fat droplets aggregate into larger globules and the emulsion becomes unstable and unsafe for use, risking occlusion of pulmonary vasculature. Commercially available IVFEs in the United States use an anionic egg yolk phosphatide emulsifier to stabilize the lipid droplets and maintain dispersion. Destabilization of the emulsion occurs in phases that begin with creaming and ends with the coalescence of the lipid particles, or “cracking” of the emulsion. A decrease in pH and the addition of divalent cations (Mg^{2+}, Ca^{2+}) alter the electrical charge on the fat droplet surface and pose a risk to the integrity of the emulsion. Although dextrose decreases the pH, the addition of amino acids provides an adequate buffer for this variable. The amount of divalent cations added to TNAs should be limited to minimize the risk of emulsion instability. Trivalent cations such as iron should never be added to a TNA parenteral nutrient formulation. PN formulations containing lipid must be assessed visually for signs of phase separation, in which the instability of the emulsion is manifested by “oiling out,” indicated by a continuous layer of oil or individual fat droplets. Fat emulsion particles have an average size of 0.5 μm. A destabilized emulsion is not visibly apparent until the lipid particles are 40 to 50 μm. Fat particles as small as 5 μm may occlude pulmonary capillaries.[43,44] Therefore, the use of a 1.2-μm filter is recommended to protect against the infusion of enlarged lipid particles.[12,43]

Table 38-4

Advantages and Disadvantages of 2-in-1 and 3-in-1 Parenteral Nutrition

	2-in-1	3-in-1
Advantages	■ Improved overall stability ■ Increased flexibility in concentrating dextrose and amino acids ■ Allows more flexibility to add higher concentrations of electrolytes ■ Better medication compatibility ■ Reduced risk of bacterial growth because of high osmolarity and acidic pH ■ Better visualization of precipitant of particulate matter. Enables the use of bacterial retention filter (0.22-micron) ■ Lower risk of catheter occlusion if IVFE is not used daily	■ All components are aseptically compounded by the pharmacy ■ Simplified regimen for the patient especially at home ■ Less supply and equipment costs ■ Less nursing time needed for administration ■ Decreased preparation cost ■ Decreased risk of contamination ■ Inhibited bacterial growth versus separate IVFE ■ Minimize infusion-related reactions from IVFE because of slower infusion rate ■ May improve lipid clearance because of slower infusion rate ■ Decreased risk of phlebitis with PPN
Disadvantages	■ Increased administration costs and time when lipids are infused separately ■ Increased risk of touch contamination ■ Increased risk of phlebitis, particularly if PPN is not co-infused with IV lipid emulsion ■ IVFE given in a piggyback manner is limited to a maximum hang time of 12 hours.[45]	■ Impaired visualization of particulat matter or precipitate because of opacity of IVFE admixture ■ IVFE is less stable—more prone t lipid separation. Admixture is less stable with concentrated electrolyte additives ■ Larger particle size of IVFE admixture. Must use 1.2-micron. Cannot use 0.22-micron bacterial retention filter. ■ Limited compatibility with medications ■ Containers with diethylhexyl phthalate should be avoided because this toxic material may be extracted by the lipid and may harm patients.

Using dual-chamber bags may extend the shelf life of TNAs because they allow the lipid to be physically separated from the dextrose, amino acids, and other additives until it is time to administer the feeding. The use of dual-chamber bags has the greatest advantage for home care settings, where up to a week's supply of parenteral feedings are prepared at one time.[43]

After preparation, TNAs should be refrigerated (4°C) to preserve stability. Once the bag is removed from the refrigerator, it may be warmed to room temperature and the contents mixed well before administration. Mixing is best accomplished by gently inverting the container up and down to ensure top-to-bottom transfer of the fluid. Vigorous shaking should be avoided because it introduces air, which can destabilize the emulsion.[43,44]

CASE 38-2, QUESTION 8: How does microbial growth differ between 2-in-1 and TNA (3-in-1) formulations?

Dextrose–amino acid PN formulations are not conducive to growth of most organisms because of their high osmolarity (>2,000 mOsm/L) and acidic pH. Lipid emulsions alone, however, are isotonic and have a physiologic pH, providing an optimal growth medium. Combining these three substrates in a TNA provides a formulation with a microbial growth potential that is intermediate between the two.[43,44] The number of CVC violations or manipulations correlates strongly with the incidence of catheter-related infections. From an infection-control perspective, the use of a single daily bag of PN formulation limits the number of manipulations of the CVC to one per day, thereby minimizing touch contamination. The Centers for Disease Control and Prevention guidelines allow TNA formulations to hang for up to 24 hours. However, because of concerns about the potential of lipid emulsions to support microbial growth, the hang time for IVFE when administered alone in a piggyback manner with 2-in-1 PN formulations is 12 hours.[43]

CASE 38-2, QUESTION 9: Design a plan to monitor the adequacy of B.B.'s specialized nutrition support and to identify and prevent adverse complications.

Routine monitoring and evaluation of nutritional status and the metabolic effects of therapy are required for patients receiving PN therapy. Nutritional goals established in the patient care plan are estimates of a patient's nutritional requirements and must be evaluated regularly to assess adequacy of therapy. Daily monitoring parameters include vital signs, body weight, temperature, serum chemistries, hematologic indices, nutrition intake, and fluid intake and output.

The adequacy of nutrition therapy should be assessed weekly. This may be accomplished through measuring serum concentrations of visceral proteins (see Table 35-2 in Chapter 35, Basics of Nutrition and Patient Assessment) such as prealbumin and albumin. Because prealbumin has a half-life of only 2 to 3 days, serum concentrations of this protein should increase weekly with adequate nutrition and improving clinical status. Albumin has a much longer half-life of 14 to 20 days that renders it less useful in reflecting an anabolic response to PN therapy. It is, however, a good indicator for morbidity and mortality.[46] Indirect calorimetry, if performed correctly, is the most accurate way to reassess energy expenditure. A method to assess adequacy of protein intake is to evaluate nitrogen balance which compares the amount of nitrogen administered to the amount of nitrogen excreted (amount "in" vs. amount "out"). The nitrogen "in" is provided by the AA component of the PN formulation. Each commercially available amino acid formulation has a slightly different amount of nitrogen per gram of amino, so the manufacturer's product information should be consulted to obtain this value. On average about 16% of amino acid is nitrogen or 1 g of nitrogen for every 6.25 g of protein. Most of the nitrogen is excreted in the urine as urea, a byproduct of protein breakdown for energy. Renal excretion of urea nitrogen increases with increasing stress. To determine the nitrogen balance, urine must be collected for 24 hours and the amount of urine urea nitrogen (UUN) measured. Some laboratories have the capability of measuring total urine nitrogen, which measures all nitrogen entities in the urine. In addition, some nitrogen lost via skin, respiration, and stool is not measurable but is estimated to be between 2 and 4 g/day.

p. 798

---

p. 799

Table 38-5

Routine Monitoring Parameters for Parenteral Nutrition

Suggested Schedule for TPN Monitoring						
Parameter	**Initial**	**Daily (Critically Ill)**	**2-3 × Weekly (Stable)**	**Weekly**	**Monthly (Home Health)**	**As Indicated**
Weight	X	X	X			
BUN, Creatinine, Glucose	X	X	X			
Na, K, Cl, HCO_3^-, Ca, P, Mg	X	X	X			
Albumin, AST, ALT, LDH, Alk Phos, Total Bili, Conj Bili	X			X		X
Prealbumin	X			X		X
Triglycerides	X			X		X
RBC count, Hgb, Hct, WBC count, Platelets	X			X		X

$$\begin{aligned}\text{Nitrogen balance} &= \text{Nitrogen in} - \text{Nitrogen out}\\ &= \text{AA (g)}/6.25 - (\text{UUN [g]} + 3\text{ g})\\ &= \text{g}\end{aligned} \qquad \text{(Eq. 38-8)}$$

Achieving a positive nitrogen balance is difficult, if not impossible, in critically ill patients; therefore, the calculation may result in a negative number or zero. For convalescing patients, a nitrogen balance of plus 2 to 4 g is acceptable. A negative nitrogen balance prompts a reevaluation of the amount of protein and energy a patient is receiving. For patients with a negative nitrogen balance, it may be helpful to increase intake of both calories and protein.

As with all tests, assessment should include monitoring several parameters, including the patient’s clinical status. Most important is the identification of trends that may alert clinicians to impending complications. A suggested schedule for monitoring is provided in Table 38-5.

CASE 38-3

QUESTION 1: C.C., a 56-year-old man, is admitted to the hospital complaining of increasing abdominal pain and vomiting. He is diagnosed with acute pancreatitis. This is his third admission for pancreatitis during the past year. His past medical history is significant for ethanol abuse, chronic obstructive pulmonary disease, and type II diabetes. His social history is significant for 2 packs/day smoking history. A NG tube is inserted, and he is to receive nothing by mouth (NPO). IV fluids are begun for hydration. During the next 5 days, C.C.’s abdominal pain subsides, his pancreatitis resolves, and he is started on an oral diet. Two days after beginning an oral diet, C.C. complains of severe abdominal pain and is vomiting. He is febrile, his WBC count has increased to 21,000/μL, and he is hypotensive, requiring large volumes of IV fluids. Furthermore, he experiences respiratory distress and requires endotracheal intubation and mechanical ventilation. His most recent arterial blood gas (ABG) is notable for pH, 7.44; Pco_2, 40 mm Hg; Po_2, 88 mm Hg; and HCO_3^-, 28 mEq/L. C.C.’s clinical presentation is consistent with severe pancreatic necrosis. A small-bore nasojejunal feeding tube is placed, and enteral nutrition therapy is begun. However, C.C. experiences severe abdominal pain and distension, and bowel sounds are absent, so the enteral feeding is discontinued. The decision is made to begin PN because C.C. is not expected to have a functional GI tract in the near future and his nutrient intake has been inadequate during his hospitalization. C.C. is 5 feet 8 inches tall, and his usual weight is 215 lb.
What adjustments should be made in determining C.C.’s energy goals?

First, C.C. is considered obese, and an adjusted body weight should be calculated and used in nutrition calculations. Obesity is defined as weight exceeding 120% of ideal body weight or a body mass index (BMI) of greater than 30 kg/m^2. C.C. weighs 215 lb, or 98 kg, which is 142% of his ideal body weight of 69 kg. BMI is determined as shown by Equation 38-9.

$$\begin{aligned} \text{BMI} &= \text{W (kg)/Height (m)}^2 \\ &= 98\ \text{kg}/(1.73\ \text{m})^2 \\ &= 32.7\ \text{kg/m}^2 \qquad \text{(Eq. 38-9)} \end{aligned}$$

Obese patients should have their weight adjusted because adipose tissue is not metabolically active. However, about one-fourth of the adipose tissue is composed of some supporting tissue that is metabolically active. Adjusted weight for obesity is calculated using Equation 38-10.[47]

$$\begin{aligned} \text{Adjusted weight} &= (0.25)(\text{Actual weight} - \text{IBW}) + \text{IBW} \\ &= (0.25)(98 - 69) + 69 \\ &= 76\ \text{kg} \qquad \text{(Eq. 38-10)} \end{aligned}$$

Using an adjusted weight will decrease the risk of overfeeding, which can further increase adipose tissue and complicate glucose management, especially in a patient with a history of diabetes mellitus. Another approach is to use the Ireton-Jones predictive equation that includes a factor for obesity. Using indirect calorimetry to obtain a measured energy expenditure may more accurately assess energy expenditure and avoid overfeeding.

C.C. is considered to be a critically ill patient. Guidelines from the American Society for Parenteral and Enteral Nutrition (A.S.P.E.N.) support permissive underfeeding (80% of estimated energy requirements) for critically ill patients to minimize the

risk of insulin resistance, infectious morbidity, and prolonged mechanical ventilation. As the patient stabilizes, the PN regimen may be increased to meet a 100% of estimated energy requirments.[21] For critically ill obese patients, the A.S.P.E.N. guidelines go a step further to support that if BMI is in excess of 30, goal caloric intake should not exceed 60% to 70% of target energy requirements or 11 to 14 kcal/kg actual body weight per day (or 22–25 kcal/kg ideal body weight per day). Protein should be provided at >2.0 g/kg IBW for BMI classes I and II and at >2.5 g/kg IBW for BMI class III.[21,48] In the case of C.C., his BMI is 32.7 (BMI Class I) so his energy goal is estimated at 22 kcal/kg of ideal body weight or approximately 1,500 kcal/day.

CASE 38-3, QUESTION 2: Is the use of lipid emulsion contraindicated in patients with pancreatitis?

Several observations have raised concern about the use of IVFE in patients with pancreatitis. The oral ingestion of fats may stimulate pancreatic exocrine function and should be restricted in patients with pancreatitis. Although hyperlipidemia has been well described in patients with alcohol-induced pancreatitis, it is unlikely that it is primarily responsible for initiating the pancreatitis. Acute pancreatitis associated with hypertriglyceridemia is most often seen in patients with hereditary or acquired defects in lipid metabolism. Furthermore, pancreatitis alone may be associated with hypertriglyceridemia.[49]

Several investigators have evaluated the effects of PN formulations containing IVFE's in patients with acute pancreatitis and have found no stimulation of pancreatic exocrine function. Furthermore, IVFE did not result in abdominal pain or relapse in patients with a history of pancreatitis. Available data suggest that IVFE are a safe and efficacious form of calories for patients with pancreatitis.[49]

While consensus has not been reached regarding the optimal composition of lipid emulsions, recent guidelines from the Society of Critical Care Medicine (S.C.C.M.) and the A.S.P.E.N. recommend that during the first week of stay within an intensive care unit, patients should receive PN formulations that do not contain soy-based lipids.[49] The addition of n-3 fatty acids, eicosapentaenoic acid and docosahexaenoic acid, to lipid emulsions is recommended because of positive effects on cell membranes and inflammatory processes.[50]

Monitoring serum triglyceride concentrations should be part of routine management for patients with pancreatitis and those receiving parenteral nutrient formulations containing lipids. Serum triglyceride concentrations should be maintained at less than 400 mg/dL with a continuous infusion of lipids and less than 250 mg/dL when checked 4 hours after the infusion for patients receiving intermittent IVFE infusions.[1,42,49] If serum concentrations exceed these parameters, consideration must be given to decreasing or eliminating the IVFE from the parenteral nutrient regimen.

CASE 38-3, QUESTION 3: What are other considerations regarding PN therapy initiation and formulation design for C.C.?

Patients with mild-to-moderate pancreatitis do not generally require nutrition support therapy. Patients with severe acute pancreatitis should have a nasoenteric tube placed and feedings initiated as soon as the volume resuscitation is complete. If tube feeding is not feasible, PN therapy should be considered and initiated after the first 5 days of hospitalization (after the peak of the inflammatory response).[21] Acute pancreatitis is a complex condition and its severity is highly variable. Severe acute pancreatitis can cause systemic inflammatory response syndrome affecting multiple organ systems often times resulting in organ failure. Compromised or failing organs may necessitate macronutrient and micronutrient adjustments in the PN formula.

Hyperglycemia is the most common complication associated with PN therapy and can be caused by a variety of factors. Patients without a history of diabetes mellitus may exhibit hyperglycemia under conditions of stress. Even greater alterations in glucose metabolism may be observed in patients with diabetes mellitus during critical illness. Stress-induced hyperglycemia may develop as a result of insulin resistance, suppressed insulin secretion, and increased gluconeogenesis and glycogenolysis.[51] Dextrose should be limited to 150 g during the first 24 hours of therapy, the amount of dextrose should not be increased until serum glucose concentrations are consistently less than 180 mg/dL, and capillary blood glucose concentrations should be monitored frequently. With a history of diabetes, coupled with acute pancreatitis, it is anticipated that C.C. will need supplemental insulin when his parenteral nutrient regimen is infused. Insulin therapy may be administered subcutaneously, intravenously with an insulin infusion, or directly in the PN formulation.[52,53] Regular insulin may be added to the PN formulation at a dose of 0.1 units per gram of dextrose as a reasonable starting point and should be adjusted to achieve serum glucose levels between 140 and 180 mg/dL.[54] Alternatively, a separate insulin infusion may be used for more aggressive glucose control. Capillary glucose monitoring is required during PN therapy at least every 6 hours and more frequently in hyperglycemic patients, and it may be necessary to provide additional subcutaneous insulin.[53,55,56]

CASE 38-3, QUESTION 4: C.C.'s current laboratory values are as follows:

Na, 137 mEq/L
K, 4.5 mEq/L
Cl, 102 mEq/L
HCO_3^-, 26 mEq/L
BUN, 9 mg/dL
Creatinine, 0.8 mg/dL
Glucose, 148 mg/dL
Ca, 8.9 mg/dL
Mg, 1.9 mg/dL
P, 2.8 mg/dL
Albumin, 3.0 mg/dL

Which electrolytes should be included in C.C.'s parenteral nutrient formulation?

Once macronutrient goals are achieved and tolerance is established, the daily management of PN therapy revolves around maintaining the patient's fluid and electrolyte needs. All concurrently administered IV fluids and medications must be considered and accurate records of volume intake and output reviewed. Electrolytes added to PN formulations are sodium, potassium, chloride, acetate (which is metabolized to bicarbonate), magnesium, calcium, and phosphate. Electrolyte requirements can vary widely and should be added to the PN formulation based on individual patient needs. However, patients without significant fluid and electrolyte losses, hepatic or renal dysfunction, or acid–base disturbances do well with standard maintenance doses of electrolytes. Electrolytes may be added individually or as commercially available combination products for maintenance doses. General guidelines for electrolyte requirements for parenteral feedings are included in Table 38-6.

CASE 38-3, QUESTION 5: What doses of multiple vitamins and trace elements should C.C. receive in his parenteral nutrient formulation?

Vitamins and trace elements should be included in PN regimens and are essential for normal metabolism and effective nutrient utilization. Guidelines for the 13 essential vitamins have been established by the Nutrition Advisory Group of the American Medical Association[57] (Table 38-7).

Table 38-6

Guidelines for Daily Electrolyte Requirements

Electrolyte	Amount
Sodium	80–100 mEq

Potassium	60–80 mEq
Chloride	50–100 mEq[a]
Acetate	50–100 mEq[a]
Magnesium	8–20 mEq
Calcium	10–15 mEq
Phosphorus (phosphate)	20–40 mmol

[a] As needed to maintain acid–base balance.

Table 38-7

Recommended Adult Daily Doses of Parenteral Vitamins

Vitamins	Dose
Fat-Soluble Vitamins	
A	3,300 IU (990 retinol equivalents)
D	200 IU (5 mg cholecalciferol)
E	10 IU (6.7 mg/dL-α-tocopherol)
K	150 mcg
Water-Soluble Vitamins	
Thiamine (B_1)	6 mg
Riboflavin (B_2)	3.6 mg
Niacin (B_3)	40 mg
Pyridoxine (B_6)	6 mg
Cyanocobalamin (B_{12})	5 mcg
Folic acid	600 mg
Pantothenic acid	15 mg
Biotin	60 mcg
Ascorbic acid (C)	200 mg

Guidelines for daily doses of the trace elements, such as chromium, copper, manganese, and zinc, have also been developed.[58] In addition to these trace elements, many practitioners provide selenium on a daily basis. Recommended doses of the trace elements are listed in Table 38-8. As with vitamins, trace elements are available as single entities or combination products. Molybdenum and iodine are also available commercially.

CASE 38-3, QUESTION 6: C.C.'s initial PN infusion is started at a rate of 40 mL/hour. Why is this slow infusion rate selected?

Standard practice for administering PN formulations containing hypertonic dextrose is to begin at a slow infusion rate of less than 250 g of dextrose during the first 24 hours for most patients and less than 150 g of dextrose for patients with known diabetes mellitus or hyperglycemia. The infusion is increased slowly during the next 24 to 48 hours to the goal infusion rate as of 1,800 mL/day as tolerated. This initial period allows the clinician to assess tolerance to the nutrient formulation components and to avoid metabolic complications, primarily hyperglycemia.[37] If C.C.'s serum glucose level consistently remains less than 180 mg/dL, the PN formulation infusion rate can be increased to his goal rate.

CASE 38-3, QUESTION 7: During the next 24 hours, a comparison of his intake and output reveals an overall negative fluid balance because a high volume of gastric fluid is being removed via the NG tube. Laboratory values at this time are the following:

Na, 138 mEq/L
K, 3.1 mEq/L
Cl, 91 mEq/L
HCO_3^-, 33 mEq/L
BUN, 28 mg/dL
Creatinine, 0.9 mg/dL
Glucose, 279 mg/dL
Ca, 7.8 mg/dL
Mg, 1.4 mg/dL
P, 1.8 mg/dL
Albumin, 2.8 g/dL

Arterial blood gas (ABG) results are pH, 7.46; PO_2, 98 mm Hg; PCO_2, 47 mm Hg; and HCO_3^-, 31 mEq/L. What factors contribute to these metabolic abnormalities?

Table 38-8

Recommended Daily Adult Doses of Parenteral Trace Elements

Trace Element	Dose
Chromium	10–15 mcg
Copper	0.3–0.5 mg
Manganese	60–100 mcg
Selenium	20–60 mcg
Zinc	2.5–5 mg

PN therapy may be associated with multiple metabolic complications. The most common abnormalities are hypokalemia, hypomagnesemia, hypophosphatemia, and hyperglycemia. The plan for PN therapy should include routine monitoring of these serum chemistries to identify complications early and institute methods to manage or prevent complications.

Hypokalemia

Hypokalemia, a common metabolic abnormality associated with the initiation of PN, usually occurs within the first 24 to 48 hours. Potassium moves, along with dextrose, from the extracellular to the intracellular space. Furthermore, building lean body mass (i.e., anabolism) requires approximately 3 mEq of potassium per gram of nitrogen provided by the amino acids. Administering dextrose promotes repletion of glycogen stores, which also requires potassium.[37,39,59]

C.C.'s decreased serum potassium concentration is compounded by metabolic alkalosis. With metabolic alkalosis, the renal excretion of potassium is increased. Additional potassium should be administered and can be provided in C.C.'s parenteral feeding or through another IV.

Hypomagnesemia

Magnesium, like potassium, is primarily an intracellular cation and is considered an anabolic electrolyte. It is common to observe decreases in magnesium serum concentrations during the administration of parenteral nutrient formulations. Synthesis of lean tissue requires 0.5 mEq of magnesium per gram of nitrogen.[37,39,59] Additional magnesium can be added to the PN formulation. However, when a TNA formulation is used, the amount of magnesium must stay within the guidelines for the cation content to maintain the stability of the lipid emulsion.

Hypophosphatemia

Hypophosphatemia occurs when phosphorus moves into the cells for the synthesis of adenosine triphosphate (ATP), an important energy carrier. Phosphorus is depleted quickly with the administration of hypertonic dextrose, especially in malnourished patients (see Case 38-2, Question 3, for discussion of refeeding syndrome). Phosphorus is used for ATP synthesis, primarily in the liver and skeletal muscle. Alkalosis also decreases phosphate stores by stimulating the phosphorylation of carbohydrates. As a component of 2,3-diphosphoglycerate, found in red blood cells (RBCs), phosphorus is necessary for the disassociation of oxygen from hemoglobin.[59]

Clinical signs and symptoms of hypophosphatemia usually occur when serum concentrations fall to less than 1.0 mg/dL. They include lethargy, muscle weakness, impaired WBC function, glucose intolerance, rhabdomyolysis, seizures, hemolytic anemia, reduced diaphragmatic contractility, and death. Moderate to severe, complicated hypophosphatemia can be managed by administering up to 0.625 mmol/kg of phosphate IV.[39,59–61] Although C.C.'s serum phosphorus is not less than 1.0 mg/dL, it is low (1.8 mg/dL), and he should receive 15 to 30 mmol of phosphate in the parenteral nutrient formulation per day. Additional supplements may be necessary to replete his phosphorus stores.[60]

Metabolic Alkalosis

C.C. has evidence of a metabolic alkalosis based on his ABG results, hypochloremia, and elevated bicarbonate level. The continued loss of fluid and hydrochloric acid from the NG tube is the most probable cause of his metabolic alkalosis. Management of this type of metabolic alkalosis is to replace the fluid and chloride through another IV. Because acetate is converted to bicarbonate and can further contribute to the alkalosis, the acetate salts in the parenteral nutrient formulation can be changed to chloride salts.[59] Nevertheless, the PN formulation generally is not the primary vehicle for adjusting and supplementing electrolytes and fluids. Instead, the fluid and electrolyte balance may be adjusted with maintenance IV fluid and electrolyte supplements.

Hyperglycemia

Hyperglycemia is the most common metabolic complication of PN therapy, especially in stressed patients. Metabolic stress increases gluconeogenesis and glycogenolysis. This increase in endogenous glucose production coupled with the administration of hypertonic dextrose in PN formulations increases the potential for hyperglycemia.[62] C.C. is at particular risk for hyperglycemia because he is diabetic, experiencing pancreatitis, and recovering from the stress of surgery.

Persistent hyperglycemia may lead to glucosuria and osmotic diuresis, resulting in dehydration and electrolyte abnormalities. Hyperglycemia compromises the immune response altering chemotaxis and phagocytosis and impairing complement function, thereby increasing risk of infection. In extreme cases, hyperglycemia progresses to hyperosmolar, non-ketotic acidosis and coma, a condition associated with 40% mortality.

Hyperglycemia can be minimized by limiting the dextrose infusion rate to less than 4 mg/kg/minute (20 kcal/kg/day).[63] Clinical evidence suggests that treatment of hyperglycemia and maintenance of euglycemia may reduce morbidity and mortality, length of stay, and hospital costs.[53,55,64–66]

CASE 38-3, QUESTION 8: In response to these serum chemistries, the electrolytes in C.C.'s parenteral nutrient formulation are changed to the following per liter: NaCl, 160 mEq; KCl, 140 mEq; phosphate as K salt, 60 mmol; $MgSO_4$, 54 mEq; and calcium gluconate, 30 mEq. How do the doses of calcium and phosphate compare with maintenance doses? What calcium and phosphate incompatibilities should be anticipated? Will the calcium and magnesium content alter the lipid stability?

Calcium and phosphate solubility is a safety concern with PN formulations. The dose of calcium ordered for C.C. is more than 3 times the usual maintenance dose (Table 38-6). This amount of calcium is not necessary because the observed hypocalcemia merely reflects C.C.'s low serum albumin concentration; therefore, less calcium is bound to albumin. C.C. probably does not have true hypocalcemia because his free (or ionized) calcium, which is critical for physiologic function, has not changed. If available, obtaining an ionized calcium concentration is advised. However, some laboratories do not have this test available. In this situation, a "corrected" calcium formulation may be used. For every 1-g/dL decrease in serum albumin concentration, there will be about a 0.8-mg/dL reduction in the serum calcium concentration.[67] For C.C., a serum calcium of 7.8 mg/dL will correct to a serum concentration of 8.8 mg/dL ([4.0–2.8 g/dL albumin][0.8] + 7.8 mg/dL calcium).

The amount of phosphate prescribed for C.C. at this time exceeds the usual recommended dose of 20 to 40 mmol/day (Table 38-7). Although C.C. has a low serum phosphorus concentration and needs additional phosphate, increasing the dosage in the parenteral nutrient formulation to 60 mmol/day may be incompatible with the calcium content, resulting in calcium–phosphate precipitation.

Numerous factors affect calcium–phosphate solubility, and caution is warranted when preparing PN formulations to ensure that solubility limits are not exceeded. If solubility is compromised, microprecipitates can occur and may cause diffuse pulmonary emboli, resulting in respiratory distress or death. Calcium and phosphate precipitation curves have been developed to assist practitioners in safe compounding practices. These guidelines help predict the points at which calcium–phosphate precipitation is likely to occur. The solubility of calcium and phosphate must be determined based on the volume of the formulation at the time the calcium and phosphate are mixed together, not the final volume. For example, if the electrolytes including calcium and phosphate are added to 1,000 mL of a dextrose–amino acid mixture and then 300 mL of IV fat is added, the calcium–phosphate solubility is based on the 1,000 mL, not the final 1,300 mL volume. In addition, some amino acid products contain phosphate ions, and these should be considered when determining calcium–phosphate solubility.[12,68]

The in vitro precipitation of calcium–phosphate depends on the type of calcium salt used in compounding, concentrations of calcium and phosphate, amino acid concentration, temperature, pH of the formulation, and infusion time. Calcium gluconate rather than the chloride salt offers enhanced calcium phosphate solubility. In solution at equimolar concentrations, calcium chloride dissociates more than calcium gluconate, thereby increasing the yield of free calcium available for binding with phosphate. Calcium and phosphate should not be added to the PN formulation in close sequence. It is recommended to add phosphate first and calcium last, thereby taking advantage of the maximal parenteral volume. The PN formulation should be agitated periodically during preparation and inspected for precipitates.[69] Other guidelines for improving the solubility of calcium are a final amino acid concentration of greater than 2.5% and a pH less than 6. An increase in the ambient temperature, such as that found in the heated isolettes within neonatal intensive care units, can facilitate the precipitation of calcium–phosphate. PN formulations should be infused within 24 hours after compounding if stored at room temperature; if refrigerated, it should be infused within 24 hours after rewarming. Increasing temperature and slow infusions may result in calcium–phosphate precipitation in the IV catheter, even if precipitation has not occurred in the infusion container.[12]

The amount of divalent cations, calcium (20 mEq) and magnesium (30 mEq), exceeds the general guidelines for maximal amounts that can be added safely to a

TNA without disrupting the stability of the lipid emulsion. A limit of 20 divalent cations per liter is a general guideline. The amount prescribed for C.C.'s

---

regimen is excessive because it provides 50 divalent cations in 1.8 L (28 divalent cations/L) and may result in a potentially unstable admixture.

Last, a 1.2-µm air-eliminating filter should be used when infusing TNA PN formulations, and a 0.22-µm air-eliminating filter should be used for non–lipid-containing admixtures.[12]

CASE 38-3, QUESTION 9: C.C. is recovering from his pancreatitis, and a small-bore nasojejunal enteral feeding tube is reinserted. Tube feeding is considered because he cannot eat by mouth because of the endotracheal tube and mechanical ventilation. How should he be transitioned from parenteral to enteral feedings?

Tube feedings can begin with a full-strength isotonic enteral feeding formulation at a slow continuous infusion rate (10-50 mL/hr and advanced by 10-25 mL/hr every 4 to 24 hours) (see Chapter 37, Adult Enteral Nutrition). Concurrently, the PN formulation should be decreased to avoid fluid overload and to keep the calorie and protein intake constant. It can be anticipated that C.C. can transition from parenteral to enteral feedings in 24 to 48 hours.

CASE 38-4

QUESTION 1: D.D., is a 43-year-old man with a 17-year history of Crohn's disease (CD). He has had several hospital admissions over the past 2 years with exacerbations of Crohn's Disease. D.D. has experienced an unintentional weight loss of 12% over the past year. He is admitted to the hospital for increasing abdominal pain, nausea, and vomiting for 9 days, and no stool output. Prior to admission D.D.'s condition was managed with mesalamine 1 gm QID and prednisone 10 mg QD. On physical examination, D.D. appears thin and his abdomen is distended. Baseline labs are as follows:

Na, 142 mEq/L
K, 4.2 mEq/L
Cl, 99 mEq/L
HCO_3^-, 15 mEq/L
BUN, 12 mg/dL
Creatinine, 0.9 mg/dL
Glucose, 114 mg/dL
Ca, 9.1 mg/dL
Mg, 1.9 mg/dL
P, 5.8 mg/dL
Albumin, 2.8 g/dL
Prealbumin, 28 g/dL
Interpret D.D.'s prealbumin level.

Although D.D.'s prealbumin level indicates his nutritional status is adequate, caution must be exercised with its interpretation. In the 1960s it was shown that prednisone administration may elevate prealbumin levels.[70] Despite his prealbumin level, D.D. has other indicators of chronic malnutrition. His albumin level is low at 2.8 g/dL. He has experienced an unintentional weight loss of 12 lbs over the past year and appears thin. Corticosteroid therapy is fairly common in patients likely to use PN solutions. These patients include patients with inflammatory bowel disease, patients being treated for cancer, and respiratory patients.

CASE 38-4, QUESTION 2: D.D. has a prolonged hospital course complicated by intra-abdominal abscesses, poor wound healing, and necrotic bowel, requiring removal of all but 82 cm of his small intestine but leaving his ileocecal valve and colon intact. D.D. is given a diagnosis of short bowel syndrome (SBS). What is the clinical significance of the presence of D.D.'s ileocecal valve and colon?

The presence of the terminal ileum and colon following small bowel resection is critical in nutritional and hydrational management as the patient may be able to tolerate a very short small intestine without TPN support. The presence of the ileocecal valve is thought to prolong intestinal transit time and serve as a barrier to bacterial reflux into the small intestine. Deficiencies of electrolytes, trace elements, and vitamins are common in Crohn's disease and influenced by the presence of the terminal ileum and colon. Deficiencies are often reflective of chronic blood loss (e.g., iron deficiency), chronic diarrhea (e.g., magnesium, selenium, zinc deficiencies), or loss of specific absorptive sites (e.g., vitamin B_{12}). There is a high prevalence of vitamin D deficiency in patients with Crohn's disease.

CASE 38-4, QUESTION 3: What issues should be addressed in the nutrition and metabolic management of this patient?

SBS occurs from extensive intestinal resection that results in inadequate bowel function to support nutrient and fluid requirements. SBS becomes clinically apparent when about 75% of the small bowel is removed. Recent studies suggest that the average length of the small intestine may be shorter than previously thought (approximately 11 feet), so SBS is best defined using a patient's symptoms and findings rather than solely on remaining length of small bowel.[71] SBS patients frequently experience diarrhea, dehydration, and nutritional deficiencies of minerals, trace elements, and vitamins (see Chapter 28, Lower Gastrointestinal Disorders). In adults, this syndrome is commonly seen in Crohn's disease, radiation enteritis, mesenteric artery infarction, adhesive obstruction, and trauma.[72] Severe malnutrition will develop without adequate nutrition support.

To maintain adequate nutrition status, D.D. will require PN until his remaining intestine begins to adapt. This adaptive period may take several weeks to months to years, with the majority of intestinal adaptation occurring within the first 2 years following massive bowel resection. Gut adaptation is enhanced by stimulation of the enterocytes with nutrients, which is best provided by small, frequent oral meals or tube feeding.[1,73,74] Sometimes the remaining intestine may never adapt, and SBS may necessitate lifelong PN therapy for survival.

A potential complication of SBS is hypersecretion of gastric fluids. The volume and acid content of gastric secretions is directly proportional to the amount of bowel resected.[79–81] The patient can experience symptoms of reflux similar to a Zollinger–Ellison syndrome with epigastric pain and burning. Medications that decrease GI tract motility (antidiarrheals) and secretions (H_2 blockers and proton pump inhibitors) are frequently necessary to reduce the volume of gastric secretions and minimize the damaging effects of hypersecretion of gastric acid. These agents are also important in the management of fluid and electrolyte imbalances because of excessive GI fluid losses. Patients with extensive small bowel resection and an intact colon, such as D.D., may experience diarrhea as a result of bile salt depletion.[1,73,74]

Octreotide may help in decreasing diarrhea in patients with SBS. Octreotide reduces a variety of GI secretions and slows jejunal transit, but the effects are often short-lasting and have not shown improved nutrient absorption.[82] It is important to be mindful that most oral medications are absorbed within the first 50 cm of the jejunum. Delayed-release medications should be avoided.

Patients with SBS are at risk for having vitamin and mineral deficiencies, especially folate, vitamin B_{12}, vitamin D, selenium, and zinc. These patients should receive supplemental vitamin B_{12} and IV parenteral or oral liquid multivitamin supplements. GI losses of trace minerals, particularly zinc and selenium, are increased in SBS, and these minerals should be supplemented.[73,74]

D.D. should be continued on PN support and will most likely need PN therapy at home to sustain his nutrient and fluid requirements. Since oral ranitidine in not an option, the treatment team

orders ranitidine 150 mg to be added to D.D.'s PN formula to manage hypersecretion of gastric fluids and diarrhea. D.D.'s fluid status must be monitored and evaluated daily for clinical signs of dehydration or fluid overload. Electrolyte abnormalities, including hyponatremia, hypokalemia, hypomagnesemia, hypocalcemia, and metabolic acidosis, should be anticipated.[74]

CASE 38-4, QUESTION 4: On hospital day 10, he presents with a fever and green, purulent fluid draining from his abdominal incision site. He is diagnosed with an enterocutaneous fistula. The fluid loss from D.D.'s fistula is about 600 mL/day. How will losses from D.D.'s fistula affect his PN?

Enterocutaneous (EC) fistulas are an abnormal communication between the intestine and the skin. Most EC fistulas occur 7 to 10 days following surgery and are classified by site of origin, output volume, etiology, and number of fistulas. Fluid, electrolyte, and trace element losses from the EC fistula will vary depending on the origin of the fistula. Losses must be accounted for and incorporated into the PN formulation or replaced through a separate IV fluid infusion.

CASE 38-4, QUESTION 5: D.D. has stabilized and his physician would like to discharge him home in a few days with the plan to continue TPN at home. D.D. is 5 feet 8 inches tall and weighs 141 lbs at discharge. Design an appropriate PN therapy for home infusion.

Home TPN has allowed patients, such as D.D., to be discharged from the hospital sooner. Candidates for home therapy must be physically and medically stable, have a strong support network in the home setting to assist with care, and have an appropriate home environment. They must be educated regarding the prescribed therapy.[75]

The first step in designing a PN regimen is to estimate energy and protein needs (see Chapter 35, Basics of Nutrition and Patient Assessment). D.D. is 10 days out from surgery, and his estimated requirements are 25 to 30 kcal/kg/day or approximately 1,600 to 1,920 kcal/day. Protein goals must include adequate nitrogen (protein) for wound healing and replacement for losses from the enterocutaneous fistula. A goal of 1.5 to 1.8 g/kg/day (96–115 g) is reasonable. Long-term systemic corticosteroid therapy is commonly seen in Crohn's patients and may cause muscle wasting. Losses of lean body mass from corticosteroids may increase amino acid requirements.

To simplify his nutrition and fluid regimen, all of D.D.'s fluids, including parenteral nutrients, electrolytes, vitamins, trace minerals, and water, should be provided in one TNA container per day. D.D.'s home PN formulation can be provided in 3,000 mL/day to meet maintenance requirements (see Case 38-1, Question 5) and to replace losses from his enterocutaneous fistula (600 mL/day). Nutrients provided include 100 g of amino acids (400 kcal); 264 g of dextrose (884 kcal); 50 g of lipid (500 kcal); and electrolytes, vitamins, and minerals to maintain normal serum chemistries. Initially, daily intake and output must be monitored; therapy should be adjusted based on this information and D.D.'s clinical status.

Adjustments in fluids and electrolytes may be needed. The fluids secreted by the GI tract are rich in electrolytes, including sodium, potassium, chloride, and bicarbonate. Measurement of the electrolyte content of the fistula fluid will determine those that must be replaced, and in what quantities. Both fluid and electrolytes should be replaced to prevent dehydration and electrolyte and acid–base imbalances.

In addition to losses of fluids and electrolytes, the trace element zinc is lost in fluid from the small intestine. Approximately 12 mg of zinc is lost in each liter of small bowel fluid, and should be replaced to prevent zinc deficiency. Furthermore, zinc may play a role in wound healing.[76] Management of enterocutaneous fistulas may include octreotide 50 to 100 mg given subcutaneously 2 or 3 times daily or added to the parenteral nutrient formulation to decrease fistula output.[77]

A home infusion pharmacy will be responsible for preparing D.D.'s PN formulations. Typically, a seven day supply of PN therapy (7 bags) is prepared and delivered to the patient's home. These formulations must be refrigerated until administration; however, formulations should be warmed to room temperature and visually inspected for particulate matter before being administered. Because some additives such as multivitamins are not stable for long periods, the patient or caregiver must add these to the PN formulation just before administration.

Patients and caregivers preparing for home PN therapy must be taught how to manage home therapy. This includes assessment of fluid status, care of a CVC, infection, and the technical aspects of administering parenteral feeding formulations.[75] Preparation for home PN includes placement of a central venous access device for long-term TPN therapy.[7,8]

CASE 38-4, QUESTION 6: What other measures can be used to simplify D.D.'s parenteral feeding regimen and encourage ambulation?

Transitioning D.D. from a 24-hour continuous PN infusion to a cyclic infusion must be considered. After D.D.'s PN regimen is formulated to meet his entire daily nutrient and fluid needs and he is stable on that regimen, his PN regimen can then be cycled. Cycling means that the PN formulation is infused for less than 24 hours per day, so that there is time free from PN therapy each day. Cycling is usually done gradually, prior to hospital discharge, and depends on the patient's ability to tolerate the changes in fluid and dextrose intake that occur when the TPN is started and stopped each day. For example, the 24-hour PN infusion is decreased to a 20-hour infusion (e.g., 8:00 PM to 4:00 PM) on cyclic PN day 1 and then the next day is decreased to a 16-hour infusion (e.g., 8:00 PM to 12:00 noon), and the next day a 12-hour infusion (e.g., 8:00 PM to 8:00 AM). With each incremental decrease in time, the infusion rate should be increased such that the total PN volume is infused each day. The infusion rate of the PN regimen is generally tapered up over 1 to 2 hours upon PN initiation to avoid hyperglycemia and tapered down over 1 to 2 hours upon PN discontinuation each day to avoid hypoglycemia. For example, a 16-hour cyclic PN infusion with a 1-hour taper up and down can be calculated by taking the total TNA volume divided by the infusion time minus 1 hour, to estimate the goal infusion rate. The goal infusion rate is then divided by 2 to get the 1 hour taper up and taper down rate. For D.D.'s 3,000 mL TNA, the regimen would start at 8:00 PM at 100 mL/hour for 1 hour, then at 9:00 PM the rate would increase 200 mL/hour for 14 hours. At 11:00 AM the following day the TNA rate would taper back down to 100 mL/hour and then at noon it would stop. Most infusion pumps used at home can automatically make these adjustments in the infusion rate. Eventually, the nutrient formulation can be infused for 10 to 12 hours during the night, leaving D.D. free from his PN infusion during the day.

Vital signs, fluid intake and output, serum electrolytes, and glucose concentrations should continue to be monitored. The serum glucose concentration should be evaluated 30 minutes to 1 hour after the PN infusion is completed to be sure that hypoglycemia does not occur.

CASE 38-4, QUESTION 7: In addition to his PN formula and ranitidine 150 mg IV, D.D. is receiving hydrocortisone 100 mg IV every 8 hours, and he now needs insulin. Can these medications or any other medications be mixed with his PN formula to simplify his medication regimen?

Patients receiving PN therapy often require concomitant drug therapy. Most patients have adequate venous access or have multiple-lumen CVCs, so that mixing medications with the parenteral nutrient formulation is not an issue. However, for some patients with limited venous access, directly added medications or piggybacking medications via a secondary infusion may be considered.

Although regular insulin, histamine type 2 (H_2)-receptor antagonists, and heparin can be added to PN formulations in some circumstances, the routine addition of medications to parenteral nutrient formulations is discouraged. Often times there are requests to add other medications to a PN admixture. Specific criteria for drug admixture with PN are listed below.[83]

1. Stability and compatibility of the drug with the specific parenteral admixture over a 24-hour period must be determined before adding the medication.
2. The medication must have appropriate pharmacokinetics and proven efficacy for continuous infusion.
3. The medication dose must have remained constant throughout the previous 24-hour period before admixture in PN.
4. There should be a stable PN infusion rate for at least 24 hours before the medication is added.
5. PN should include appropriate labeling to avoid pharmacotherapeutic problems associated with abrupt discontinuation of PN.

CASE 38-4, QUESTION 8: After receiving home PN for 3 weeks, D.D.'s liver function tests are found to be elevated. Current values are as follows:

Bilirubin, 0.8 mg/dL
Aspartate aminotransferase, 70 units/L
Alanine aminotransferase, 90 units/L
Alkaline phosphatase, 100 units/L
Could his PN be contributing to these abnormalities?

Elevations in liver function tests are common in adults receiving long-term PN therapy and may be noted as early as 2 to 3 weeks after beginning therapy. The abnormalities are usually mild and transient and do not progress to significant liver dysfunction in adults. The predominant type of hepatobiliary dysfunction is steatosis (fatty liver), whereas other patients develop cholestasis or cholelithiasis (biliary obstruction). Liver-associated enzyme elevations usually resolve when PN therapy is discontinued. Rarely does this dysfunction proceed to hepatic failure.[35,78]

Other than avoiding overfeeding with carbohydrate and lipid, there are few options to prevent or manage PN-associated liver abnormalities. Potential management options include metronidazole and supplements of ursodeoxycholic acid, choline, and carnitine. Transitioning to a lipid emulsion containing n-3 fatty acids should also be considered. Patients with progressive liver disease may be candidates for liver and small bowel transplantation.[78]

The elevations in D.D.'s liver enzymes are not of concern at this time because they are less than 3 times normal. However, since D.D. has been on home PN for 3 weks and his wounds have healed, it is time to decrease his energy and protein intake to maintenance requirements (20-25 kcal/kg/day and 0.8-1.0 g/kg/day of protein). Liver enzymes should be monitored weekly. Because he may not need lifelong PN therapy, the mild elevations are likely to resolve.

It is important to keep in mind that the liver is the primary organ involved with digestion, metabolism, and storage of nutrients. When the functional capacity of the liver is compromised (e.g., cirrhosis), macronutrient intolerance and imbalances may occur. The patient may experience hyperglycemia, hypoglycemia, variations in blood lipid levels, and accumulation of amino acid metabolites (ammonia).

CASE 38-4, QUESTION 9: After 10 months of receiving home TPN, D.D. suffers a fall and fractures his wrist. Fracture of the wrist from a fall raises suspicions of compromised bone density. Subsequent DEXA scan reveals a bone density T-Score of –3.1. Can these results be caused by long-term PN? What are other complications of long-term parenteral therapy?

Long-term complications of PN are adverse effects associated with PN lasting greater than 3 months. The most common complications include central catheter complications (infection or occlusion), metabolic bone disease, and hepatobiliary disease.[84]

The exact cause of metabolic bone disease in long-term PN is unknown; however, its origins appear to be multifactorial. The predominant risks factors for metabolic bone disease in D.D. include Crohn's disease, the medications used to manage it (e.g., corticosteroids) coupled with the use of long-term PN therapy.[85] Both osteoporosis and osteomalacia have been associated with long-term PN use. Osteoporosis is the most common form of metabolic bone disease and is because of loss of bone mass. Osteomalacia is the softening of bones and generally occurs as the result of vitamin D deficiency. A combination of both osteoporosis and osteomalacia may occur. Deficiencies in micronutrients such as calcium, magnesium, and vitamin D are risk factors. Historically, bone abnormalities were thought to be caused by aluminum toxicity. However, as aluminum has been nearly eliminated from TPNs, metabolic bone disease remains an issue. High amino acid concentrations and TPN cycling cause increased renal calcium excretion. Other factors include abnormalities in the handling of calcium, phosphorus, and vitamins D and K.

Central catheter–related complications can vary from occlusion to central catheter–related sepsis. Both of these complications are related to CVC care and are a surrogate measure of overall catheter care.[86] Occlusion develops from fibrin and/or lipid deposits. The consequences of catheter occlusion range from diminished flow to complete occlusion necessitating removal of the catheter. Central catheter infections are associated with the amount of times the catheter is accessed for PN administration and blood sample removal. Patients with CVC infections usually present with symptoms and signs such as pyrexia and tachycardia during PN infusion. The causes of central catheter infections are bacterial and are usually because of skin flora, Staphylococcus epidermis and Staphylococcus aureus. If CVC-related sepsis is suspected, then the CVC being used should be discontinued and peripheral and central cultures taken, while antimicrobial therapy is started pending culture results.[85]

The incidence of hepatobiliary complications associated with long-term PN ranges from 19% to 75%. These complications are variable, with patients experiencing chronic elevations in liver enzymes to advanced liver disease (fibrosis and cirrhosis). Liver disease associated with PN is termed intestinal failure–associated liver disease (IFALD). IFALD is divided into nonnutrient and nutrient-related causes. Nonnutrient causes of IFALD can include medications, biliary obstruction, bacterial overgrowth, and intrinsic liver disease. Nutrient-related IFALD can be caused by overfeeding, nutrient toxicities, and deficiencies. Nutrient toxicities associated with IFALD include manganese, aluminum, and soybean oil. Some nutrient deficiencies associated with IFALD are taurine, choline, carnitine, and essential fatty acids. The most common histological finding in IFALD is steatosis followed by cholestatic stasis, fibrosis, and finally cirrhosis. Hepatic steatosis is associated with both under and overfeeding, so the importance of ensuring the correct amount of calories is of utmost importance.[84]

SECTION 8 | Dermatologic Disorders

Section Editor: Timothy J. Ives

39

Dermatotherapy and Drug-Induced Skin Disorders

Richard N. Herrier and Daniel R. Malcom

CORE PRINCIPLES		CHAPTER CASES
①	The accurate assessment of dermatologic conditions is primarily based on the appearance and location of the skin lesion, plus age, sex, symptoms, and current and past personal and family history.	**Case 39-1 (Question 1)** **Figure 39-1** **Tables 39-3, 39-4, 39-5**
②	Dry skin (xerosis) is a common condition that may occur alone or with a variety of dermatologic disorders and requires appropriate treatment depending on geographic location.	**Case 39-2 (Question 1)** **Table 39-6**
③	The selection of topical corticosteroid is based on the nature of the lesion (wet vs. dry), the concentration of the corticosteroid, the nature of the vehicle, the corticosteroid potency, the location of the lesion, and the thickness of the epidermis.	**Case 39-3 (Questions 1, 2)** **Figure 39-1, Tables 39-1, 39-2, 39-3, 39-4, 39-5, 39-7**
④	Topical corticosteroids can cause a variety of adverse effects and adverse reactions that may require adjustment of therapy including changing products or discontinuing their use.	**Case 39-4 (Questions 1–3)** **Tables 39-7, 39-8, 39-9**
⑤	Atopic dermatitis is a common dermatologic condition characterized by eczematous lesions, dry skin, and intense pruritus. Most patients have a family or personal history of other atopic diseases such as asthma and allergic rhinitis. Atopic dermatitis is primarily treated with topical corticosteroids and emollients.	**Case 39-5 (Questions 1–5)** **Tables 39-3, 39-5, 39-6, 39-7, 39-10**
⑥	Allergic contact dermatitis is one of the most common dermatologic conditions seen by pharmacists. Drugs (neomycin), plants (Rhus), chemicals, detergents, metals (nickel), and organic products (latex) are common causes. Treatment consists of removal of the antigen and use of topical or systemic corticosteroids.	**Case 39-6 (Question 1)** **Case 39-7 (Questions 1, 2)** **Tables 39-3, 39-5, 39-7, 39-10, 39-11**
⑦	Medications are a common cause of a variety of dermatologic disorders. Timing relative to medication ingestion and principles of dermatologic assessment are important to identify potential life-threatening adverse reactions.	**Case 39-8 (Question 1)** **Tables 39-8, 39-11**

ANATOMY AND PHYSIOLOGY OF THE SKIN

The skin is the largest organ in the body and constitutes, on average, 17% of a person's body weight. The skin's thickness ranges from 3 to 5 mm. Figure 39-1 shows a cross section of the anatomy of human skin. Physiologically, the major function of skin is to protect underlying structures from trauma, temperature variations, mechanical penetrations, moisture, humidity, radiation, and invasion of microorganisms. There are three layers of skin: epidermis, dermis, and subcutaneous tissue.[1–5]

Epidermis

The major function of the epidermis is to serve as a barrier. The epidermis keeps chemicals and other substances from penetrating into the body and prevents the loss of water from the skin and underlying tissues.

The stratum corneum, which is composed of dead cells, provides the greatest resistance to the percutaneous absorption of chemicals and drugs. It behaves as a semipermeable membrane through which drugs are absorbed by passive diffusion. Factors that can enhance drug absorption are hydration of the skin and damage to the stratum corneum. In general, the greater the damage to the stratum corneum, the greater is the absorption of topically applied drugs. Skin diseases affecting only the epidermis heal without scarring.[1–5]

Hypodermis (Subcutaneous Tissue)
Blood Vessel

Figure 39-1 Cross section of the anatomy of human skin.

Dermis

The dermis is composed of collagen fibers and ranges in thickness from 1 to 4 mm. The major function of the dermis is to protect the body from mechanical injury and to support the dermal appendages (i.e., sweat and sebaceous glands, hair follicles) and the epidermis. It also provides capillary, lymphatic, and nerve supply to the skin and its appendages. The dermis contains large amounts of water, thus serving as a water storage organ as well. Importantly, all but the most superficial injuries to the dermis generally result in scarring as the wound heals.[1–5]

Drugs passing through the epidermis penetrate directly into the dermis and may be absorbed into the general circulation through the capillary network. Only small amounts of topically applied drugs enter the dermis via the sweat glands or the pilosebaceous units.

Subcutaneous Layer

The subcutaneous layer supports the dermis and epidermis and serves as a fat storage area. This layer helps regulate temperature, provide nutritional support, and cushion the outer skin layers.[1–5]

INFLAMMATORY LESIONS

One of the dermatologic axioms regarding therapy is particularly useful in selecting dosage forms: “If it is wet, dry it; if it is dry, wet it.” Paradoxically, wet dressings (e.g., Burow solution) are most useful in drying acute, inflamed lesions because they draw out fluid as they evaporate. Ointment-type bases increase hydration to an affected area by slowing water evaporation from the skin and are most useful for chronic, lichenified, scaling lesions. The choice of vehicle for chronic lesions is often based on what the patient has found to work best or is willing to use. Frequently, patients with chronic dermatologic conditions use multiple types of vehicles concomitantly (e.g., cream bases, which are drying because they are oil in water emulsions) during the day, because they are cosmetically acceptable, and ointment bases at night (greasy, but better emollients).

Acute Lesions

Acute inflammatory lesions can be characterized by vesiculation, erythema, swelling, warmth, pruritus, oozing, or weeping. Generally, depending on the part of the body involved, the more severe the dermatitis, the milder is the initial topical therapy would be. For instance, cool water in the form of a wet dressing, soak, or bath is more effective as the initial therapeutic agent than a potent topical corticosteroid applied to a warm, erythematous, weeping dermatitis.[1–6]

Subacute and Chronic Lesions

Subacute lesions are characterized by decreasing vesiculation and are often covered with crusts. They still require cleaning and drying with aqueous preparations, but for a shorter duration than with acute lesions. Chronic inflammatory lesions are characterized by erythema, scaling, lichenification, dryness, and pruritus. There are no absolute rules for treating chronic lesions. If the lesion is dry, an oleaginous or occlusive base should be used.

DERMATOLOGIC DRUG DELIVERY SYSTEMS

Dermatologic formulations are available in a variety of forms: solutions, suspensions or shake lotions, powders, lotions, emulsions, gels, creams, ointments, and aerosols. Each dermatologic delivery vehicle has specific characteristics and uses based on the type, relative acuteness, and location of the lesion.

Solutions

Solutions provide evaporative cooling and vasoconstriction, with resultant mild antipruritic effects. They soothe and cool inflamed skin, dry oozing lesions, soften crusts, aid in cleaning wounds, and assist in the drainage of purulent wounds. Aqueous solutions are most useful for acutely inflamed, oozing lesions; erosions, and ulcers, and are often applied as wet dressings. In most instances, solutions should be the sole therapy until the oozing or weeping subsides. If other topical medications are applied, they will be washed away and will not provide the desired effect. The most commonly used solutions are normal saline (0.9% NaCl) and aluminum acetate 5% solution (Burow solution) diluted 1:10 to 1:40.

The most important component of a solution is water. Although active or inert substances may be added to solutions, the cleansing, drying, and cooling effect of water provides the major therapeutic benefit. Some of the products (e.g., Burow solution) also have astringent properties that alter the skin surface and interstitial spaces to cause contraction and wrinkling. Water penetration is reduced to minimize edema, inflammation, and exudation. Table 39-1 lists the most commonly used solutions. Boric acid should not be used as a topical agent because it can be absorbed through the skin, causing systemic toxicity.[6]

Table 39-1

Solutions for Wet Dressings or Drying Weeping Lesions

Agent[a]	Strength	Preparation (H_2O)	Germicidal Activity	Astringent Activity	Comments
Normal saline	0.9% NaCl	1 tsp NaCl per pint H_2O	None	None	Inexpensive; easy to prepare
Aluminum acetate	5%	Dilute to 1:10–1:40 (0.5%–0.125%)			
(Burow solution) (Domeboro packets/tablets)		One packet or tablet to a pint of water yields a 1:40 solution; two packets or tablets yield a 1:20 solution	Mild	+	
Potassium permanganate	65- and 330-mg tablets	Dilute to 1:4,000–1:16,000; 65-mg tablet to 250–1,000 mL; 330-mg tablet to 1,500–5,000 mL	Moderate	None	Stains skin, clothing
Silver nitrate	0.1%–0.5%	1 tsp of 50% stock solution to 1,000 mL will yield a 0.25% solution	Good	+	Stains; can cause pain
Acetic acid[b]	1%	Dilute 1 pint of standard 5% household vinegar with 5 parts H_2O	Good	+	Unpleasant odor; can be irritating

[a] Although many substances are added to wet dressings, the cleansing and drying effect of the water is the major benefit.

[b] Used primarily for Pseudomonas aeruginosa infections.

Source: Arndt KA, Hsu JHS, eds. Manual of Dermatologic Therapies: With Essentials of Diagnosis. 8th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2014.

Depending on the affected area and its size, a patient may soak the affected area directly in the solution for 15 to 30 minutes 3 to 6 times per day. If larger areas are involved or if the affected area cannot be easily soaked (e.g., a shoulder), a clean towel or cloth soaked in the solution (lightly wrung out) is directly applied to the lesion(s) as a wet dressing. The soaked cloth should be left in place for 5 to 10 minutes and then resoaked in the solution and reapplied. The patient may repeat this procedure for 15 to 30 minutes 3 times daily. Solutions applied with a cloth should have the cloth material wrapped around the lesions several times, if possible. If large areas are involved, the patient may draw a bath, add appropriate amounts of medications found in Table 39-1, and soak for 15 to 30 minutes 3 to 6 times/day. In general, no more than one-third of the body should be soaked in this manner at any time. Evaporation can concentrate solutions, potentially making them too irritating to use. Small volumes of a 1:40 concentration of Burow solution left standing open at room temperature after 30 to 60 minutes may yield a 1:10 solution. For this reason, wet dressings should always be freshly prepared (i.e., within 24 hours), kept in closed containers, and never reused. When drying the affected area after a wet dressing has been used, care must be taken not to irritate the inflamed skin by rubbing it with a towel; rather, the area should be patted dry gently with a soft, clean towel.[6]

Baths

In addition to wet dressings and soaks, topical solutions can be applied to large areas of the body through bathing. In using this type of treatment, the bath should be about half full. Soothing and antipruritic colloidal bath additives may be used to treat widespread eruptions. Colloidal oatmeal, in the form of 1 cup of oatmeal (e.g., Aveeno) mixed with 2 cups of cold tap water and poured into 6 inches of a lukewarm bath, produces a pleasing and soothing bath. Alternatively, a starch bath using two cups of hydrolyzed starch (e.g., Linit, a mixture of equal parts baking soda and hydrolyzed starch) may also be used. Epsom salt baths, made by dissolving three cups of magnesium sulfate in 6 inches of lukewarm water in a tub, are useful in treating pyodermas, furuncles, and necrotic acne (especially when the back, shoulders, and buttocks are affected).

Many different bath oils are available: Alpha-Keri, Domol, Lubriderm, and Nutraderm. Adding the oil directly to the bath is not recommended because it makes the tub slippery and potentially dangerous. The concentration of the oil in the water becomes almost insignificant anyway (5–10 mL in 20–40 gallons). Approximately 5 to 10 mL of bath oil may be applied directly to wet skin on leaving a bath and patted dry with a towel for a more significant effect. This is most useful in preventing and treating mild cases of xerosis (dry skin). With moderate-to-severe cases of xerosis, additional topical oleaginous products are generally required to improve the condition.

Powders

Powders are drying and cooling, absorbing moisture and creating more surface area for evaporation. They are used mainly in intertriginous areas (e.g., groin, under the breasts, or in skin folds) to decrease friction, which can cause mechanical irritation. The liberal use of powders on bedridden patients helps prevent pressure ulcers (bedsores). They also are useful in the treatment of chafing, tinea pedis (athlete's foot), tinea cruris (jock itch), and diaper dermatitis (diaper rash).

Powders can be applied with a cotton puff or shaker. Care should be taken to minimize breathing the powder because this can lead to respiratory tract irritation, particularly in infants. Powders that contain starch or cellulose (which are hygroscopic) should be washed off before reapplication, because continued buildup can produce mechanical irritation. Corn starch-containing powders should not be used for intertrigo (inflammation of body folds—thighs, armpits, under breasts, or enlarged abdomen; aggravated by heat, moisture, and maceration) because starch can serve as a substrate for Candida albicans. Powders should not be applied to oozing lesions because they tend to cake into hard granules, making them difficult and painful to remove, and promoting maceration. The most commonly used powder is talc.

Lotions

Lotions are suspensions or solutions of powder in a water vehicle. They are usually cooling and drying, but may provide some lubrication, depending on the formulation. Lotions are used to treat superficial dermatoses, especially if there is slight oozing. They are useful if large or intertriginous areas are affected, and they are especially advantageous in the treatment of conditions characterized by significant inflammation and tenderness. In these situations, creams or ointments may cause pain on application. Lotions are also useful for hairy areas of the body and scalp. Generally, lotions not containing corticosteroids are applied 3 or 4 times daily, with each fresh application placed over previous application, unless there is significant oozing present, which could promote caking of dried solid ingredients. If this is the case, the area should be cleansed before repeat application. Because many lotions are suspensions, it is advisable to shake the lotion well before application. Generally, 6 ounces of lotion covers the entire body of an average adult.[6]

Liquid Emulsions

Liquid emulsions can be divided into two classes: oil-in-water (o/w) and water-in-oil (w/o) emulsions. Creams are generally oil-in-water emulsions, whereas ointments are water-in-oil emulsions. Because the fraction of oil increases, the viscosity of the emulsion will also increase.

The indications for liquid oil-in-water emulsions (e.g., Keri Lotion, Cetaphil) are similar to those for lotions and creams, except that this dosage form provides greater occlusion and is more useful in conditions in which dry skin predominates. Liquid water-in-oil emulsions (e.g., Nivea, Eucerin, or Lubriderm) have similar indications to ointments, except they can be applied more easily than ointments. Water-in-oil emulsions are most useful in conditions in which dry skin predominates; application to hairy or intertriginous areas should be avoided. As with lotions, 6 ounces of a liquid emulsion will cover all exposed skin on an average adult.[7]

Gels

Gels are a form of ointment (semisolid emulsion) that contain propylene glycol and carboxypolymethylene. They are clear, nongreasy, nonstaining, nonocclusive, and quick drying. They are thixotropic (i.e., become thinner with rubbing and may sting on application). Gels are most useful when applied to hairy areas or other areas such as the face or scalp, where it is considered cosmetically unacceptable to have the residue of a vehicle remain on the skin. Because of their ingredients, gels tend to be more drying.

Creams

Creams are the most commonly used vehicle in dermatology. Most are oil-in-water emulsions and are intended to be rubbed in well until they vanish (vanishing creams). Because creams are drying and do not provide much occlusiveness, they are most often recommended for subacute lesions and occasionally for chronic lesions without significant lichenification. The most common mistake made by patients when applying creams is that they use too much or do not rub them in fully. Generally, if the cream can be seen on the skin after application, the patient has made one or both of these application mistakes and the preparation is wasted or the patient is not getting the full therapeutic benefits.

Ointments

Ointments are made of inert bases such as petrolatum or may consist of droplets of water suspended in a continuous phase of oleaginous material (i.e., water-in-oil emulsions such as Aquaphor or Polysorb). Ointments are most useful on chronic lesions, relieving dryness, brittleness, and protecting fissures owing to their occlusive properties. They should not be used on acutely inflamed lesions. Ointments should not be applied to intertriginous, burns, or hairy areas because they tend to trap heat and promote maceration. Ointments are greasy and may be cosmetically unacceptable.

Table 39-2

Appropriate Dermatologic Vehicle Selection Across the Range of Dermatologic

Lesions

Range of Lesions	Range of Vehicles
Acute inflammation: Oozing, weeping, vesication, edema, pruritus	Aqueous vehicles and water, and then powder solutions, lotions, sprays, and aerosols
↓	↓
Subacute inflammation: Crusting, less oozing, pruritus	Creams, gels
↓	↓
Chronic inflammation: Lichenification, dryness, erythema, pruritus, scaling	Ointments

Aerosols

Aerosols are the most expensive and inefficient way to apply dermatologic medications. Their only advantage over other dosage forms is that they do not require direct mechanical contact with the skin and may be useful if application causes intolerable pain for the patient. If an aerosol is used, it should be shaken well before use, and the patient should be cautioned not to spray the product around the face where it could get into the eyes or nose or be inhaled. Generally, aerosols should be sprayed from approximately 6 inches above the skin in bursts of 1 to 3 seconds. Aerosols are also useful for application to hairy areas if a special application nozzle is used. Aerosols have a drying effect and should not be used for a long period.

Selection of a Delivery System

Dermatologic vehicles should be matched to the type of lesion for which they will be used. Acute lesions require aqueous vehicles until the lesions become dry. Subacute lesions also benefit from aqueous vehicles, but for shorter periods before switching to creams or gels. Chronic lesions usually require ointments because of their dry, lichenified characteristics. Although there are exceptions, usually due to patient preferences, these principles are depicted in Table 39-2.

ASSESSING THE DERMATOLOGIC PATIENT

CASE 39-1

QUESTION 1: C.B., a 23-year-old, 66-kg woman, complains of a rash. What types of questions should C.B. be asked to help determine the appropriate diagnosis and treatment?

The diagnosis of dermatologic conditions can be simplified by considering six primary factors: appearance (what the lesions look like, pattern of the lesions);

location or distribution of the lesions on the body; symptoms, both local and systemic; history of the present condition as well as related conditions; age of the patient; and patient sex. Direct observation of the skin lesion, plus C.B.'s responses to questions about these factors, will allow an appropriate diagnosis and treatment plan.

Table 39-3

Dermatologic Lesions, Definitions, and Clinical Examples

Name	Definition	Examples
Primary Lesions		
Macule	Nonpalpable, flat, change in color, <1 cm	Freckles, flat moles
Patch	Nonpalpable, flat, change in color, >1 cm	Vitiligo, "café au lait" spots, chloasma
Papule	Palpable, solid mass, may have change in color, <1 cm	Verrucae, noninflammatory acne (comedone), raised nevus
Nodule	Palpable, solid mass, most often below the plane of the skin, 1–2 cm	Erythema nodosum, severe acne
Tumor	Palpable, solid mass, >2 cm, most often above and below the plane of the skin	Neoplasms
Plaque	Flat, elevated, superficial papule with surface area greater than height, >1 cm	Psoriasis, seborrheic keratosis
Wheal	Superficial area of cutaneous edema, fluid not confined to cavity	Urticaria (hives), insect bite
Vesicle	Palpable, fluid-filled cavity, <1 cm, filled with serous fluid (blister)	Herpes simples, herpes zoster, contact dermatitis
Bulla	Palpable, fluid-filled cavity, >1 cm, filled with serous fluid (blister)	Pemphigus vulgaris, second-degree burn
Pustule	Similar to vesicle, but filled with purulent fluid	Acne, impetigo, folliculitis
Special Primary Lesions		
Comedone	Plugged opening of sebaceous gland	Acne, blackhead, whitehead
Cyst	Palpable lesion filled with semiliquid material or fluid	Sebaceous cyst
Abscess	Accumulation of purulent material in dermis or subcutaneous layers of skin; purulent material not visible on surface of skin	
Furuncle	Inflammatory nodule involving a hair follicle, following an episode of folliculitis	Small boil
Carbuncle	A coalescence of several furuncles	Large boil
Secondary Lesions		
Erosion	Loss of part or all the epidermis	Ecthyma
Ulcer	Loss of epidermis and dermis	Stasis ulcer

Fissure	Linear crack from epidermis into dermis	Tinea pedis
Excoriation	Self-induced linear, traumatized area caused by intense scratching	Atopic dermatitis, extreme pruritus
Atrophy	Thinning of skin with loss of dermal tissue	Striae
Crusts	Dried residue of pus, serum, or blood from a wound, pustule, or vesicle	Impetigo, scabs
Lichenification	Thickening of epidermis, accentuated skin markings, usually induced by scratching or chronic inflammation	Atopic dermatitis, allergic contact dermatitis

Appearance (morphology)

Table 39-3 provides a listing of common dermatologic lesions, their respective definitions, and some well-known clinical examples. Lesions may also be classified as either primary or secondary. Primary lesions are lesions because they first appear on the skin, whereas secondary lesions develop from primary lesions. The ability to recognize and describe specific lesions is critical to a successful diagnosis and communication regarding response to therapy.

In addition, many lesions present in a particular distribution or pattern. Poison ivy lesions are commonly distributed linearly. Herpetic lesions are so typical that the term herpetiform is used for lesions caused by other conditions that have a herpes-like distribution. The specific size of the lesion is also important in assessing a patient's condition. Dermatologic terms related to lesion distribution or pattern are shown in Table 39-4. The lesion's consistency (firm vs. soft), borders, and color are also important diagnostic considerations.

Location

Certain lesions or conditions usually occur in specific body locations, usually due to physiologic reasons. Table 39-5 provides a list of anatomic sites with common dermatoses occurring in those locations. For example, diseases of the sebaceous glands (e.g., acne, seborrheic dermatitis, rosacea) occur only in sites with high concentrations of sebaceous glands, such as the scalp, head, neck, chest, and umbilicus. Atopic dermatitis shows a predilection for the flexor surfaces of the body (i.e., antecubital and popliteal fossae).

Symptoms

Most skin conditions have only localized symptoms with the most common symptom being pruritus. Occasionally, localized burning or pain is the predominant symptom.

Table 39-4

Descriptive Dermatologic Terms

Term	Characteristics	Examples
Annular	Ring shaped	Tinea
Acneiform	Acne-like	Acne vulgaris
Arcuate	Shaped like an arc	Syphilis
Circinate	Circular	Tinea
Confluent	Lesions run together	Psoriasis, tinea
Discrete	Lesions remain separate	Psoriasis, tinea
Eczematous	General term for dry, red flaky, or lichenified skin without clear border	Chronic allergic contact dermatitis, atopic dermatitis
Geographic	Shaped like islands or continents; map-like	Generalized psoriasis
Grouped	Lesions clustered together	Herpes
Herpetiform	Appears like herpes simplex	Herpes simplex
Intertrigo	Irritant dermatitis in skin folds	Diaper dermatitis
Iris	Looks like a bull's-eye, lesion within a lesion, target lesion	Erythema multiforme
Keratotic	Horny thickening	Psoriasis, corn, callus
Linear	Shaped in lines	Poison ivy
Multiform	More than one type or shape of lesion	Erythema multiforme
Papulosquamous	Papules with desquamation	Psoriasis
Serpiginous	Snake-like lesions	Cutaneous larva migrans
Zosteriform	Appears like herpes zoster	Herpes zoster

Table 39-5

Common Skin Diseases by Body Location

Location	Skin Diseases
Scalp	Seborrheic dermatitis, dandruff
Face	Acne, rosacea, seborrheic dermatitis, perioral dermatitis, impetigo, herpes simplex, atopic dermatitis
Ears	Seborrheic dermatitis
Chest or abdomen	Tinea versicolor, tinea corporis, pityriasis rosea, acne, herpes zoster
Back	Tinea versicolor, tinea corporis, pityriasis rosea
Genital area	Tinea cruris, scabies, pediculosis, condyloma acuminate (venereal warts)
Extremities	Atopic dermatitis (cubital and popliteal fossa)
Hands	Tinea manuum, scabies, primary irritant contact dermatitis, warts
Feet	Tinea pedis, contact dermatitis, onychomycosis
Generalized or localized	Primary irritant or contact dermatitis, photodermatitis

History

Although a diagnosis may often be made from morphology, location, and symptoms, the patient history provides useful diagnostic and therapeutic information. Similar to the historical information obtained for any acute medical problem, the following questions should always be asked:

1. When and how did the problem start?
2. How has it progressed or changed since its onset? How have the lesions changed in size, color, appearance, or severity?
3. What is the patient’s past and current medical history? What other symptoms might indicate that this is a dermatologic manifestation of a systemic disease?
4. What are the patient’s other symptoms?
5. What kind of allergies does the patient have?
6. What makes the condition worse or better?
7. What events or happenings have occurred with the onset or worsening of the condition (e.g., increased stress, exposure to new products, recent travel, and changes in climate)?
8. What have you used to treat the condition, and how have the treatments worked?
9. How did the patient use any previous therapy, and for how long did they use it?

Age

Many conditions occur predominantly in certain age groups, such as acne in neonates and those ages 11 to 20 years, seborrheic dermatitis in neonates and those ages 11 to 12 years, rosacea in those older than 30 years, and atopic dermatitis primarily in children younger than 6 years. In fact, atopic dermatitis begins and ends before 6 years of age in 95% of patients. It is equally important to realize that many conditions, such as primary irritant and allergic contact dermatitis, occur independent of age. In addition, the skin of children and patients older than 65 years is more penetrable, thus more responsive and more susceptible to adverse effects from therapy with topical agents. Topical therapeutic agent potency and delivery systems must be carefully evaluated before usage.

Sex

Although most dermatologic conditions occur in both sexes, sometimes frequency and severity are sex dependent. Rosacea

---

occurs more frequently in women, but is often more serious in men.

XEROSIS

CASE 39-2

QUESTION 1: C.R., a 64-year-old woman, requests something for dry skin on her shoulders and back. She has had this problem for a number of years. It is generally not a problem in the summer, with most symptoms troubling her in the winter. She denies any visible rash. When asked what makes it better, she tells you bathing provides some temporary relief. She has no other medical conditions and only takes an occasional aspirin for "arthritis." How would you advise C.R. to manage this condition?

C.R.'s complaints represent a common problem of the elderly, xerosis (dry skin). The seasonal cycle described is frequently called "winter itch." Most cases of dry skin are caused by dehydration of the stratum corneum.[7,8] Cold temperatures decrease the indoor humidity because of increased use of central heating, or living in a low humidity climate, such as in Arizona, dry out the outer layers of the skin. Given fact that bathing (moisture) provides temporary relief points to xerosis as the most likely cause.[7,8] The location of the itching, the lack of a visible rash, the relief with bathing, and no chronic diseases rule out most other causes of xerosis (e.g., atopic dermatitis, diabetes mellitus). However, given her age and sex, hypothyroidism remains a possibility. Table 39-6 gives general recommendations for the treatment of dry skin.

TOPICAL CORTICOSTEROIDS

Table 39-7 lists the most common topical corticosteroid preparations by their degree of potency according to the Stoughton–Cornell classification system.

Indications

A topical corticosteroid is often the drug of choice for many inflammatory and pruritic eruptions. In addition, topical corticosteroids are useful with hyperplastic and infiltrative disorders. The following conditions generally respond well to topical corticosteroids: allergic contact dermatitis, atopic dermatitis, psoriasis, and seborrheic dermatitis.

Contraindications

The following conditions (predominantly infectious etiologies) are worsened by topical corticosteroids: acne vulgaris, ulcers, scabies, warts, molluscum contagiosum, fungal infections, and viral infections.

CASE 39-3

QUESTION 1: AJ is a 54-year-old male who has suffered intermittently from plaque psoriasis for almost 20 years. Most lesions have been coin-sized in various locations (mostly elbows and knees). Normally, gentle removal of the scales and application of 1% hydrocortisone ointment has been effective over several weeks during which it disappears. He has averaged less than a lesion a year. He saw a dermatologist once 18 years ago. Six weeks ago a much larger hand-sized lesion developed on his elbow. The usual treatment has been ineffective. What are the relevant biopharmaceutic considerations for selecting a topical corticosteroid for A. J.?

Table 39-6

General Recommendations for Treatment of Dry Skin

1. Use room humidifiers.
2. Keep room temperature as low as comfortable to prevent sweating and water loss from the skin.
3. Keep bathing to a minimum (every 1–2 days) with warm, but not hot, water. After bathing, the patient should immediately apply an emollient. When the skin is soaked for 5 to 10 minutes, the stratum corneum can absorb as much as 6 times its weight in water. Application of an emollient immediately after bathing will trap the water in the skin and reduce dryness.
4. Eliminate exposure to solvents, drying chemicals, harsh soaps, and cleaners. These substances remove oils from the skin and reduce its barrier function. Because the barrier function is lost, water loss from the skin is increased up to 75 times higher than normal. Exposure to cold, dry winds will also enhance water loss.
5. Apply emollients 3 to 6 times a day, especially after bathing to help retain moisture in the skin from bathing.
6. The selection of emollients depends on the atmospheric moisture content of the region. In dry parts of the western United States where humidity is very low, water-in-oil emollients such as Lubriderm, Eucerin, or Nivea are preferred because the high oil content prevents the loss of moisture from the skin. In those areas, a general rule is to avoid products in which glycerin is one of the top four ingredients on the label because glycerin is hygroscopic and in low humidity will pull moisture out of the dermis, leading to drier, cracked skin. In areas with higher humidity such as the eastern United States, glycerin in both types of emollients pulls moisture from the atmosphere into the skin. Regardless of region, if application of an emollient appears to be ineffective, switching to a product with less glycerin and more oil may resolve the dryness.
7. If scaling is a problem, a keratolytic (Lac-Hydrin, AmLactin) or a higher-strength, urea-containing preparation (20%) may be useful.

Topical corticosteroids are classified into potency categories (Table 39-7). The relative potency assigned to a topical corticosteroid is determined by the ability of the preparation to penetrate the skin after release from the vehicle, the intrinsic activity of the corticosteroid at the receptor, and the rate of clearance from the receptor.[10] Activity of corticosteroids may be enhanced by the use of a more occlusive vehicle, the addition of penetration-enhancing substances (i.e., petrolatum, propylene glycol), and modifications of the steroid molecule. Hydrocortisone has been modified in several ways to enhance potency. The addition of a fluorine atom at the 6, 9, and 21 positions protects the steroid ring from metabolic conversion, resulting in more potent activity. The addition of a double bond between the first and second carbon atoms slows metabolism, increasing duration of action. The introduction of an acetonide bond or lipophilic ester groups increases skin penetration. Many newer topical corticosteroids have incorporated one or more of these molecular changes, resulting in increased-potency agents and a growing armamentarium of agents.[9–13]

Topical corticosteroids penetrate into the stratum corneum by passive diffusion, which varies considerably, depending on thickness of the stratum corneum over the part of the body to which the preparation is applied. When a standard hydrocortisone preparation was applied to various parts of the body, absorption was found to be 0.14% on the plantar surface of the foot, 1% on the forearm, 4% on the scalp, 7% on the forehead, 13% on the cheeks, and 36% on the scrotum. Because penetration is high in the groin, axillae, and face, lower-potency nonfluorinated topical preparations such as hydrocortisone 0.5% to 1% should be used on these areas.[9–13] In areas where penetration is poor, owing to thicker stratum corneum, such as the elbows, knees, palms, or soles, higher-potency preparations should be used.[9–13]

Table 39-7

Topical Corticosteroid Preparations by Stoughton–Cornell Classification of Potency

Corticosteroid	Example Brand Name(s)	Vehicle
1 (Most Potent) no more than 2 weeks' use		
Betamethasone dipropionate	Diprolene 0.05%	Ointment, optimized vehicle
Clobetasol propionate	Temovate 0.05%	Cream, ointment, optimized vehicle
Diflorasone diacetate	Psorcon 0.05%	Ointment
Halobetasol propionate	Ultravate 0.05%	Cream, ointment
2		
Amcinonide	Cyclocort 0.1%	Cream, lotion, ointment
Betamethasone dipropionate	Diprolene AF 0.05%	Cream
Betamethasone dipropionate	Diprosone 0.05%	Ointment
Desoximetasone	Topicort 0.25%	Cream, ointment
Desoximetasone	Topicort 0.05%	Gel
Diflorasone diacetate	Florone, Maxiflor 0.05%	Ointment
Fluocinonide	Lidex 0.05%	Cream, ointment, gel
Halcinonide	Halog 0.1%	Cream
Mometasone furoate[a]	Elocon 0.1%	Ointment
Triamcinolone acetonide	Kenalog 0.5%	Cream, ointment
3		
Amcinonide	Cyclocort 0.1%	Cream, lotion
Betamethasone	Benisone, Uticort 0.025%	Gel
Betamethasone benzoate	Topicort LP 0.05%	Cream (emollient)

Betamethasone dipropionate	Diprosone 0.05%	Cream
Betamethasone valerate	Valisone 0.1%	Ointment
Diflorasone diacetate	Florone, Maxiflor 0.05%	Cream
Fluocinonide	Cutivate 0.005%	Ointment
Fluticasone propionate	Lidex E 0.05%	Cream
Halcinonide	Halog 0.1%	Ointment
Triamcinolone acetate	Aristocort A 0.1%	Ointment
Triamcinolone acetate	Aristocort HP 0.5%	Cream
4		
Betamethasone benzoate	Benisone, Uticort 0.025%	Ointment
Betamethasone valerate	Valisone 0.1%	Lotion
Desoximetasone	Topicort-LP 0.05%	Cream
Fluocinolone acetonide	Synalar-HP 0.2%	Cream
Fluocinolone acetonide	Synalar 0.025%	Ointment
Flurandrenolide	Cordran 0.05%	Ointment
Halcinonide	Halog 0.25%	Cream
Hydrocortisone valerate[a]	Westcort 0.2%	Ointment
Mometasone furoate[a]	Elocon 0.1%	Cream
Triamcinolone acetonide	Aristocort, Kenalog 0.1%	Ointment
5		
Betamethasone benzoate	Benisone, Uticort 0.025%	Cream
Betamethasone dipropionate	Diprosone 0.02%	Lotion
Betamethasone valerate	Valisone 0.1%	Cream
Clocortolone	Cloderm 0.1%	Cream
Fluocinolone acetonide	Synalar 0.025%	Cream
Flurandrenolide	Cordran 0.05%	Cream

Fluticasone propionate	Cutivate 0.05%	Cream
Hydrocortisone butyrate[a]	Locoid 0.1%	Cream
Hydrocortisone valerate[a]	Westcort 0.2%	Cream
Prednicarbate	Dermatop 0.1%	Cream
Triamcinolone acetonide	Aristocort 0.25%	Cream
6		
Alclometasone dipropionate	Aclovate 0.05%	Ointment
Betamethasone valerate	Valisone 0.1%	Lotion
Desonide[a]	Tridesilon 0.05%	Cream
Fluocinolone acetonide	Synalar 0.01%	Solution
Triamcinolone acetonide	Kenalog 0.1%	Cream, lotion

7 (Least Potent)		
Hydrocortisone[a]	Generic 0.5%, 1.0%, 2.5%	Cream, ointment
Dexamethasone	Decadron 0.1%	Cream

[a]Nonfluorinated corticosteroid.

The stratum corneum acts as a reservoir, precluding the need for more than twice daily application. In low-potency preparations, this reservoir effect persists for several days, and with the most potent preparations under occlusion, the effects may persist for up to 14 days.[9–13] The clinical implication of this reservoir effect on chronic conditions is a cumulative effect with repeated application of topical corticosteroids. As a result, the number of applications per day can be reduced, and less potent preparations can be used after the acute inflammatory process has been brought under control. It also allows less frequent administration to maintain remission.

For A.J, a high-potency cream (class 2 or 3 as listed by Stoughton–Cornell class of corticosteroid potency in Table 39-7) should be used because the thicker stratum corneum over the elbow, the presence of scales and a raised plaque decreases penetration.

When equal amounts of a corticosteroid are incorporated into ointments, gels, creams, and lotion bases, the gel and ointment preparations are generally more active than creams and lotions.[9–13] However, with the increased use of optimized vehicles, that rule is not as true as in the past. The addition of certain substances enhances penetration and potency. Using these principles, pharmaceutical manufacturers have increasingly developed optimized vehicles that maximize diffusion of individual corticosteroids into the stratum corneum. Unfortunately, these optimized bases may be labeled as ointments, creams, or gels. Therefore, for new products, the only reliable way to ascertain potency is to consult the manufacturer's literature for its Stoughton–Cornell classification. Increasing the concentration of a corticosteroid in a preparation also increases its potency, but not in a linear fashion.

CASE 39-3, QUESTION 2: Given A.J.'s larger lesion and the failure of his usual therapy should occlusive therapy be used? What complications could develop from occlusion? How should the use of occlusion be explained to A.J.?

Occlusion

Occlusion increases the hydration of the skin and resultant absorption of corticosteroid preparations, thus producing a heightened therapeutic effect. Generally, occlusion can be accomplished by the following: (a) selecting an ointment-based corticosteroid, (b) applying a nonmedicated ointment base over a corticosteroid preparation (gel, cream, lotion, or aerosol), 30 minutes after applying the corticosteroid, or (c) by enveloping the medicated area with plastic (e.g., plastic wrap, gloves, or plastic suit). Occlusion is best used for chronic lesions that are thick and scaly, in which drug absorption is impaired, such as psoriasis. Increasing the hydration of the skin (with a shower or bath) also increases the effects of medications immediately applied after the bath or shower. An appropriate recommendation for A.J. would be fluocinonide ointment 0.05% applied twice daily to only the psoriatic plaques.[4,6,9–13] For other conditions, for example, atopic dermatitis, several hours of occlusion are all that are necessary to increase potency, these relatively short periods of occlusion can be clinically useful. Occlusion can be uncomfortable and can lead to sweat retention and an increased risk of bacterial and fungal infections. To reduce these problems and the chances of systemic adverse effects, occlusion should not be maintained for more than 12 hours in a 24-hour period. Occlusion should not be used for acute lesions, which already have increased absorptive capability and need the vasoconstrictive effects of cooling first.

Pharmacists and practitioners tend to underappreciate that both cloth and disposable diapers are powerful occlusive devices. Therefore, only low-potency nonfluorinated topical corticosteroids should be used in the diaper area for no more than 24 to 48 hours in the rare instances of severe diaper dermatitis not responding to conservative treatment. Use of topical corticosteroids to enhance the effectiveness of antifungals in the face of diaper dermatitis complicated by fungal infection is only theoretic and does not enhance the efficacy of anticandidal antifungals, but does increase the risk of local, potentially irreversible disfiguring local adverse effects of topical corticosteroids.

Adverse Drug Effects

Although relatively infrequent, both localized (i.e., at the application site) and systemic adverse effects (from percutaneous

---

absorption) can be caused by topical corticosteroids. The risks for adverse reactions are influenced by the potency of preparation used, frequency of application, duration of use, anatomic site of application, and individual patient factors. Any of the previously discussed factors that increase potency, such as inflammation and occlusion, increase the chances of adverse effects.[9]

CASE 39-4

QUESTION 1: K.L. is 54-year-old male, recently diagnosed with mild Parkinson disease, presents severe case of seborrheic dermatitis involving the ears, scalp line, forehead, and nasal labial folds. The areas are quite inflamed and red with yellow greasy scales. K.L. is upset with the way it looks. Because suppressing the cause of the disease, the yeast, malassezia furfur, will take some time, it is decided to initially use a topical corticosteroid to reduce the redness and improve K.L.'s appearance. What would be an appropriate choice of topical corticosteroid for K.L.?

The biggest concern in K.L. is the potential for epidermal and dermal atrophy (thinning of the skin), telangiectasia (small red or purple clusters of dilated capillaries), localized fine hair growth, bruising, hypopigmentation, and striae. These local complications can result from repeated application of topical corticosteroids.[12] Epidermal changes consisting of a reduction in cell size may begin within several days of therapy and are generally reversible after therapy is stopped.[10] Exposed areas (face) and thin-skinned areas (groin) are most vulnerable to dermal and epidermal atrophy.

Dermal atrophy generally takes several weeks to occur and can be reversed in some cases, depending on how long the patient has used the corticosteroid, and on individual host factors such as skin age. Dermal atrophy can be reversible within 2 months after stopping the corticosteroid.[12]

Telangiectasia, which occurs most often on the face, neck, groin, and upper chest, may not be reversible after stopping corticosteroid therapy. Striae, which occur most commonly in the cubital and popliteal fossa, groin, axillary, and inner thigh areas, are usually permanent.[12] Fine hair growth may be particularly bothersome to female patients using corticosteroid preparations on the face. This problem is generally reversible after stopping therapy. Hypopigmentation, predominantly a problem of dark-skinned patients, is generally reversible after therapy is discontinued.[12]

Especially in thin-skinned areas such as the face, fluorinated corticosteroids are more likely to cause these localized reactions because of their increased-potency than nonfluorinated corticosteroids. Therefore, whenever possible only nonfluorinated topical corticosteroids should be used in thin-skinned areas for the shortest possible time. Because the use of corticosteroids is expected to last less than a week, the risk of developing local complications is minimal with a nonfluorinated product.

Because the lesions are on the face, a nonfluorinated corticosteroid such as hydrocortisone valerate or mometasone should be used to minimize the potential for adverse effects in this thin-skinned area. Although there is minimal oozing and weeping, his sensitivity to appearance would indicate a cream might be more appropriate.

CASE 39-4, QUESTION 2: K.L. calls the next day and complains of a burning sensation lasting for about 30 minutes after each application. He wants to know whether this is potentially an allergic reaction.

Because of the time course of the burning sensation in L.K. (starting the first day and lasting only 30 minutes), it is doubtful that he is actually allergic to this product and points to the cream being the cause. To remedy this situation, L.K. should continue to apply it and if it continues for the next 24 hours to call again. Creams applied to inflamed areas can cause burning initially. Because the inflammation lessens, the burning generally subsides. If the burning persists, an ointment can be substituted, or the cream. If the reaction continues with a new product, an allergy workup may be necessary and patch testing could be considered.

Cortisol is endogenously secreted by the adrenal gland and is essential to life. As a result, allergic reactions to topical corticosteroid preparations are rare. When allergic symptoms do occur, they are generally not caused by the corticosteroid, but rather the preservatives (e.g., paraben) or other ingredients in the formulation or the base (e.g., lanolin). Allergic sensitization can occur within 2 weeks of therapy, but may be difficult to diagnose because the corticosteroid can modify the allergic reaction.[14] One should suspect an allergic reaction if lesions change appearance after starting therapy, if healing does not occur within the expected time, or if the condition improves and then abruptly gets worse. In atopic dermatitis, most case reports of allergic reactions (dryness, itching, burning, or irritation) to topical corticosteroids are nonspecific reaction.[14] The use of creams or gels may cause excessive dryness, burning, and irritation. Switching to an ointment can alleviate those symptoms. Allergic individuals are more likely to react to the vehicle base than the active corticosteroid ingredient.

ACNE

CASE 39-4, QUESTION 3: After several weeks of continuous corticosteroid and adjuvant therapy, K.L.'s seborrheic dermatitis has disappeared, but he has developed four pustules and two closed comedones on his forehead and multiple pustules on his nasal labial folds. What problems from the use of topical corticosteroid therapy on the face does this represent?

The face is particularly vulnerable to corticosteroid adverse effects because of enhanced penetration.[12] Acne, acne rosacea, and perioral dermatitis can develop after several weeks to months of application. Corticosteroid-induced conditions can generally be distinguished from naturally occurring disorders because lesions are uniformly at the same level of development throughout the affected area and are present only in areas treated with the corticosteroid. Generally, steroid acne and perioral dermatitis resolve after discontinuing the drug. Application of corticosteroid preparations (particularly the potent preparations) to areas around the eye can lead to increased intraocular pressure, glaucoma, cataracts, increased risk of ocular mycotic infections, and exacerbation of preexisting herpes simplex infections.[12]

Because K.L.'s original disorder was also treated with topical selenium sulfide shampoo to the face and the scalp to suppress the cause of his seborrheic dermatitis, the corticosteroid can be discontinued.

ADRENAL AXIS SUPPRESSION AND RISK OF INFECTION

Systemic adrenal axis suppression from topically applied corticosteroids appears to be more of a theoretic risk than a practical one in adults, except when the highest-potency preparations are used,[15] or other risk factors are present (Table 39-8). Although suppression has been reported with use of mild to moderately potent agents, these cases can be attributed to excessive use or to application of corticosteroids over large areas of the body for prolonged periods under occlusion. If suppression does occur, it reverses within 2 to 4 weeks after application is stopped. Patients using more than 45 g/week of a high-potency corticosteroid are at risk for adrenal axis suppression.[15] Therefore, the use of preparations such as clobetasol should be limited to no more than 45 g/week for 2 weeks or less. In addition, these preparations should not be used under occlusion and should be reserved for dermatoses that are unresponsive to less potent preparations.

Table 39-8

Risk Factors for Systemic Adverse Effects from Topical Corticosteroids

Duration of application
Prolonged application (>3–4 weeks)
Potency of corticosteroid
Weak or moderately strong, 100 g/week without occlusion
Very potent, >45 g/week without occlusion
Application location
Thin stratum corneum results in easier penetration (eyelids, forehead, cheeks, armpits, groin, and genitals)
Age of patient
Very young children and elderly people have very thin epidermis
Manner of application
Occlusion
Presence of penetration-enhancing substances
Propylene glycol
Salicylic acid
Urea
Condition of the skin
General factors
Compromised liver function
Uremia

Because young children absorb corticosteroids to a greater extent than adults, they have a greater risk of developing adrenal axis suppression and other systemic adverse effects.[15] To reduce this risk, low-potency topical preparations should be used in children, and their use should be limited to short periods. Patients whose corticosteroid clearance is impaired (e.g., liver failure) should also use hydrocortisone and be monitored closely for signs of systemic toxicity.[12]

The risk of developing an Addisonian crisis during surgery or at other times of stress secondary to adrenal suppression from topical steroids is extremely low.

Patients who have used potent topical corticosteroids over large areas of their bodies (>30%) or those who have used occlusion are at greater risk (see previous discussion) and are often given systemic hydrocortisone prophylactically before surgery.[15]

PROPER APPLICATION OF TOPICAL CORTICOSTEROIDS

Because overuse of topical corticosteroids leads to local and/or systemic effects and underuse results in suboptimal treatment, the amount of corticosteroid required to treat certain anatomic areas of the body has long been an issue of debate and discussion.[16,17] To prevent overuse in clinical practice, patients are typically given subjective instructions to apply topical products "sparingly" or "in a thin layer or coat" and left up to the patient or caregiver's interpretation.

The fingertip unit (FTU) was devised as a means of standardizing the way practitioners and pharmacists alike thought about how to prescribe topical corticosteroids and counsel patients on appropriate use. One FTU is defined as the amount of ointment (or other semisolid topical formulation) squeezed from a tube with a 5-mm diameter nozzle (standard in manufacturing), applied from the first distal skin crease to the tip of the index finger of an adult.[18–20] This amount is roughly equivalent to 500 mg of medication. The FTU can serve as a helpful starting point for how much product is used. Because lesions rarely conform to the exact anatomic areas in Table 39-9, adjustments need to be made based on the specific area involved. For example, in an adult with atopic dermatitis on the cubital fossa of both arms, the table does not provide that exact measurement. Because one FTU covers both sides of a hand and the cubital fossa is approximately hand-sized, the patient should be instructed to apply 0.5 FTU to each cubital fossa once or twice daily depending on the specific preparation. Although use of the FTU concept is not a panacea, it does provide a more objective benchmark to help patients more consistently apply the correct amount of product and avoid overuse. Use of the FTU concept must be accompanied by counseling and reinforcement based on the specific individual medication received, size and location of the lesion, and the desired goals of therapy. In addition, the FTU concept can be used to determine the amount to be dispensed to cover a treatment period.

Table 39-9

Fingertip Unit Charts for Adults and Children

Fingertip unit measures for use in adults[3]	
Area of body	**FTU per dose**
Face and neck	2.5
Torso and abdomen (front of trunk)	7
Back and buttocks (back of trunk)	7
One arm (front and back)	3

One hand	1
One leg (front and back)	6
One foot	2

Adult fingertip unit measures for use in children (by age of child)[4,5]				
	3–6 months	**1–2 years**	**3–5 years**	**6–10 years**
Face and neck	1	1.5	1.5	2
Arm and hand	1	1.5	1	2.5
Leg and foot	1.5	2	3	4.5
Trunk (front)	1	2	3	3.5
Trunk (back including buttocks)	1.5	3	3.5	5

Summary of Principles of Topical Corticosteroid Therapy

The following principles are used to guide the choice of agent and application technique (Table 39-7 and Table 39-9):

- Due to the reservoir effect of the stratum corneum, topical corticosteroids should b applied no more than twice daily. Increasing the application from twice daily to 4 times daily does not produce superior responses, is more expensive, and may lead to increased frequency of topical and systemic adverse effects.[10]
- Preparations should be rubbed thoroughly and, when possible, applied while the skin contains optimal moisture (e.g., after bathing and drying off).[6] Hydration of the skin increases percutaneous absorption and the resultant therapeutic effect of topical corticosteroids.
- Appropriate-strength preparations should be used to control the condition. For maintenance, most dermatologic conditions requiring topical corticosteroids can be managed with medium- or low-potency corticosteroid preparations (i.e., 1% hydrocortisone or a low-strength fluorinated corticosteroid such as triamcinolone acetonide 0.025%).[10,11]
- Occluded areas and certain, thin-skinned areas of the body, such as the face and flexures, are more prone to the development of adverse effects.[9,11] If corticosteroids must be used on the face flexures or other thin-skinned areas, hydrocortisone or other nonfluorinated topical corticosteroids should be used to reduce the probability of adverse effects. These nonfluorinated corticosteroid products are highlighted in Table 39-6.
- Children, elderly patients, and patients with liver failure are at risk for systemic corticosteroid toxicities. In addition, patients who use the highest-potency

preparations for longer than 2 weeks are susceptible to percutaneous absorption and systemic toxicity including Addison syndrome upon sudden discontinuation.[9–14]

- With chronic conditions such as atopic eczema or allergic contact dermatitis, it is best to discontinue therapy gradually. This reduces the potential for rebound flares of topical lesions.[6]

Atopic Dermatitis

CASE 39-5

QUESTION 1: P.K., a 17-year-old boy, presents to a dermatology clinic with 5% of his body covered with a pruritic, eczematous rash. There is extensive involvement of popliteal and cubital fossae bilaterally. There is evidence of excoriation with cosmetic disfigurement in the cubital fossae, and on his cheeks, with a history or frequent bouts of impetigo. P.K.'s mother and aunt have asthma. One sister (L.K.), age 15, has seasonal allergic rhinitis and eczema. His father and younger brother, age 11, appear to have no atopic manifestations. A rash was first noted 1 month after birth. The cheeks of the face were the only area affected, and the rash continued with varying degrees of severity until the age of 2 years, when it spontaneously resolved. A similar rash reappeared at age 12, was diagnosed as atopic dermatitis, and has not disappeared since that time. P.K. experienced seasonal allergic rhinitis beginning at age 6 years. He has had a difficult time trying to follow provided nondrug recommendations for eczema. He has used over-the-counter topical hydrocortisone cream to treat flare-ups during the years.

On physical examination, P.K. is a well-nourished, well-developed, adolescent boy with no abnormal physical findings other than marked allergic shiners, pale boggy nasal mucosa, and Dennie–Morgan folds noted near the eyes, plus extensive skin lesions. Oozing, crusted, excoriated areas caused by scratching, with erythematous, eczematous, lichenified eruptions, are his face and the flexor aspects of both arms and legs. There is some evidence of a secondary bacterial infection in both cubital fossae and on portions of the left leg. The presenting history, symptoms, and signs are characteristics of atopic dermatitis (eczema). Describe characteristics of atopic dermatitis and explain the significance of P.K.'s family and medical history because it relates to this disorder.

Atopic dermatitis, a form of eczema, can be acute or subacute, but is more commonly a chronic pruritic inflammation of the epidermis and dermis. Approximately two-thirds of the patients have a personal or family history of allergic rhinitis, eczema, or asthma. Sixty percent of patients are affected within the first year of life, 30% by 5 years of age, with the remaining 10% experiencing atopic dermatitis between 6 and 20 years of age. Atopic dermatitis in infants may be a prelude to the development of other atopic disorders later in life (i.e., allergic rhinitis or asthma). Presence of these disorders many times is the key to differential diagnosis. About 80% of patients with atopic dermatitis have a type I (immunoglobulin E [IgE]-mediated) hypersensitivity reaction occurring because of the release of vasoactive substances from both mast cells and basophils that have been sensitized by the interaction of the antigen with IgE. An allergy workup is rarely helpful in determining the allergen. The disorder affects 0.5% to 1.0% of the general population, although its prevalence in children is 5% to 10%. In infants and young children, the dermatitis often occurs on the face and sternal area of the chest. In older children and adults, it tends to localize to the flexural areas, especially the cubital and popliteal fossae with the neck and face involved in more severe cases.[21]

Pruritus is the hallmark of atopic dermatitis. Atopic dermatitis has been described as “the itch that rashes, rather than the rash that itches.” In other words, the itching precedes the rash. The constant scratching leads to a vicious cycle of itch-scratch-rash-itch, with bacterial colonization and infections intertwined. Chronically, untreated atopic dermatitis leads to lichenification of the affected areas. Wool, detergents, soaps, a change in room temperature, and mental or physical stress can precipitate itching. Patients tend to have dry skin (xerosis) all over the body. This is attributable to a reduced water-binding capacity and a higher transdermal water loss. Xerosis is worsened during periods of low humidity, such as winter in northern latitudes. Treating the xerosis can prevent or control the disease in mild or episodic cases.[21,22]

P.K.’s family and medical history are classic for atopic dermatitis. His family history is significant for asthma, allergic rhinitis, and atopic dermatitis. He had his initial outbreak at the age of 1 month and then experienced seasonal allergic rhinitis after his dermatitis went into remission. His skin examination reveals findings of both acute and chronic atopic dermatitis, with typical lesion location and description.

Product Selection

CASE 39-5, QUESTION 2: P.K. received a prescription for halcinonide 0.25% cream, 30 g, to be applied at bedtime to nonfacial areas and mometasone furoate cream 0.1%, 30 g, twice daily to the facial lesions. Based on pertinent biopharmaceutic considerations, why is this prescription appropriate for P.K.?

Results from P.K.’s treatment regimen might be improved by providing more frequent (twice daily) application or a more potent preparation to control inflamed lesions. Once any weeping is stopped, a less potent preparation in the ointment form should be used for maintenance and the number of applications may be reduced. Because of the reservoir effect, control can be maintained in many cases with intermittent regimens such as once daily, every other day, or every third day use of topical corticosteroids. In addition, intermittent regimens can involve alternating corticosteroids and agents such as topical pimecrolimus or tacrolimus to maintain control and minimize adverse effects of either agent.

Because the calcineurin inhibitors are as potent as mid-potency topical corticosteroids without causing atrophy, telangiectasias, or striae, many dermatologists would use either tacrolimus or pimecrolimus on the face in preference to mometasone.[22]

Topical Antibiotics with Corticosteroids

CASE 39-5, QUESTION 3: P.K.'s atopic dermatitis presentation is complicated with areas of erythematous, honey-colored, crusted lesions on his arm, and leg. Can a corticosteroid and an antibiotic preparation be used together? What are the risks associated with topical antibiotics?

It is determined that P.K. has impetigo superimposed on his atopic dermatitis. Because impetigo can be treated with topical antibiotics such as mupirocin, combination therapy with a corticosteroid–antibiotic preparation would appear to be a logical choice. Although mupirocin may be an appropriate alternative for some topical dermatologic infections, the current over-the-counter topical antibiotics (bacitracin, neomycin, and polymyxin) are ineffective for most dermatologic infections and are indicated only for the prophylaxis of skin infections. In addition, because staphylococcal toxins act as superantigens, eliciting the production of IgE, thus worsening the atopic dermatitis, almost all clinicians treat atopic dermatitis-associated impetigo with oral antibiotics such as dicloxacillin, macrolides, or cephalexin, in combination with topical corticosteroids for the atopic dermatitis.[22] Oral antibiotics reduce the bacterial counts faster and have a lower incidence of recurrent impetigo compared with topical agents. In areas in which community methicillin-resistant Staphylococcus aureus rates are high, more effective antibiotic therapy might be indicated as an alternative. P.K. would most likely benefit from a treatment course of an oral antibiotic plus a topical corticosteroid preparation.

P.K. is prone to repeated infections and atopic dermatitis flares because his skin is colonized with staphylococci. Many dermatologists upon clearance of the impetigo would initiate dilute bleach baths. These consist of 5- to 10-minute baths twice a week, made by adding 120 cc (1/2 cup) of household bleach (6%) to a full bathtub (approximately 40 gallons) to create a 0.005% solution. Because of the variety of tub sizes, the amount of bleach should be adjusted to the size of the bathtub and the amount of water in the tub.[23]

Pruritus

CASE 39-5, QUESTION 4: As stated in Case 39-5, Question 1, one of P.K.'s complaints is pruritus. What could you recommend for relief of pruritus?

As previously noted, pruritus (itching) is the most common cutaneous symptom in atopic dermatitis.[21] Scratching, which can damage or fatigue receptor nerve endings, is the most common method of relieving pruritus. Topically applied local anesthetics or antihistamines could also be effective in dulling the sensation. However, this approach is often disappointing, probably because the intact epidermis poorly absorbs the salt forms of these drugs. In addition, low concentrations are used in many over-the-counter preparations. If adequate concentrations of local anesthetics are used (lidocaine 3%–4%), pruritus or pain may be reduced for up to 45 minutes.

These agents are most useful for relieving pruritus or pain for short periods (e.g., when trying to go to sleep at night).[21] A serious drawback to the use of topical benzocaine and antihistamine preparations is their propensity to induce allergic contact dermatitis.[24]

P.K. could also try cold water or ice cubes, which effectively relieve pruritus via vasoconstriction, as do products containing aluminum acetate (Burow solution), tannic acid, or calamine. A cool bath may be useful for the relief of pruritus from dermatologic lesions if they are widespread.

Moisturizing mixtures such as Eucerin, Nivea, Lubriderm, or even simply mineral or baby oil are useful in the treatment of pruritus caused by dry skin in patients with atopic dermatitis. Bathing should be restricted to avoid washing away normal body oils, the drying effect of water, the irritant effect of alkaline soaps, and the trauma of toweling.[6]

Topical corticosteroid applications can be very effective if dermatologic lesions exist. They reduce inflammation, which helps soothe the affected area.

Systemic antihistamines are effective antipruritic agents, although their major beneficial effect may be attributable to sedation. The newer, nonsedating antihistamines are notably ineffective at relieving itch, with the exception of cetirizine.[25] There is disagreement over which antihistamine or antiserotonin agents are most effective for treatment of pruritus.[21,25,26] Oral hydroxyzine is a commonly used antihistamine; doses of 10 to 25 mg 3 to 4 times a day are commonly used. Oral cyproheptadine is another option. There is little evidence that antihistamines are effective in treating non–histamine-mediated pruritus, except that their inherent sedative effect may be somewhat beneficial in all pruritic conditions. Doxepin, a tricyclic antidepressant with potent H_1-blocking properties, is valuable as a second-line antihistamine topically or systemically if others fail.[27] Because P.K.'s pruritus is worse at night, as is typical with atopic dermatitis, the use of any of the three H_1-blockers mentioned at bedtime would be appropriate.[22]

Nondrug Recommendations for Atopic Dermatitis

CASE 39-5, QUESTION 5: In addition to prescriptions for topical corticosteroids, a systemic antibiotic (cephalexin 500 mg 4 times daily for 10 days), and an oral antihistamine (hydroxyzine 25 mg, one to two tablets by mouth at bedtime as needed), what nondrug interventions should be suggested for P.K.?

The general goals of therapy for atopic dermatitis are to decrease pruritus, suppress inflammation, and moisturize the skin. The nondrug recommendations shown in Table 39-10 are useful adjuncts and mainstays for use between disease flares for patients such as P.K. with atopic dermatitis or any other irritant dermatitis. Often careful attention to nonpharmacologic measures can markedly reduce the incidence of disease flare. Because even nonlesional skin in patients with atopic dermatitis has reduced moisture, the use of emollients should include all skin surfaces.[28]

Table 39-10

Nondrug Recommendations for Patients with Atopic Dermatitis or Other Irritant Dermatoses28

- Clothing should be soft and light. Cotton or corduroy is preferred. Wools and coarse, heavy synthetics should b avoided.
- Heat should be avoided because it often makes eczema worse. The environment should be well ventilated, coc and low in humidity (30%–50%). Rapid changes in ambient temperature should be avoided.
- Bathing should be kept to a minimum (no longer than 5 minutes), and the patient should use a nonirritating soap (e.g., Basis soap). A colloid bath or the use of appropriate amounts of bath oil may be useful.
- The skin should be kept moist with frequent applications of emollients (e.g., Lubriderm, Nivea, Aquaphor, Eucerin, or petrolatum).
- Primary irritants such as paints, cleansers, solvents, and chemical sprays should be avoided.

P.K. should be warned to avoid people with active herpes simplex infections because severe disseminated infections can occur.

Tachyphylaxis and Calcineurin Inhibitors

Clinicians commonly misdiagnose tachyphylaxis due to corticosteroids. Failure of topical corticosteroids to clear difficult atopic dermatitis after an initial improvement may give the false impression of tachyphylaxis, when the actual problem is a primary failure of the treatment.[29] This could be caused by either inappropriate application technique by the patient or the choice of a product with inadequate potency. Tachyphylaxis can occur within 1 week of therapy, but generally takes several weeks to a month to occur.[29] To treat this problem, patients should discontinue the corticosteroid for a week and restart at an appropriate dose. Alternatively, patients may be switched to topical tacrolimus or pimecrolimus.

Topical tacrolimus or pimecrolimus is an effective alternative to moderate-potency topical corticosteroids and is safe for use in children.[22,23,27] In addition to inhibitory effect on cytokine production, calcineurin inhibitors result in decreased immunologic response to antigens. Transient burning, erythema, and pruritus are the most common adverse effects. Neither pimecrolimus nor tacrolimus causes skin atrophy, making them attractive alternatives for patients with lesions on the face and the neck. Issues regarding the long-term safety of these products have led the U.S. Food and Drug Administration to place a black-box warning in the manufacturer’s literature regarding a potential increased cancer risk.[22]

ALLERGIC CONTACT DERMATITIS: POISON IVY, POISON OAK, OR POISON SUMAC

Contact dermatitis is an inflammation of the skin that occurs when a substance comes in direct contact with the epidermal surface. The most common form is irritant contact dermatitis caused solvents or other chemicals that irritate the skin resulting red, painful lesions, for example, dish pan hands, diaper dermatitis. Allergic contact dermatitis is a type IV delayed hypersensitivity reaction controlled by allergen-specific T cells. The resulting dermatitis is pruritic and many times vesicular in nature.[1–6]

Poison ivy (Rhus) dermatitis is a major cause of allergic contact dermatitis in the United States, exceeding all other causes combined. Other allergens include latex, leather, nickel, and laundry detergents. It is estimated that 50% to 95% of the population is sensitive to the plants to some degree. The severity of the condition varies from mild discomfort to an extremely painful, debilitating condition. Rhus dermatitis is caused by sensitization to an allergic substance in the leaves, stems, and roots of poison ivy, poison oak, and poison sumac plants. All three plants contain the same sensitizing oleoresin, urushiol oil, which contains pentadecacatechol, the actual sensitizing agent. Therefore, the dermatitis caused by the three different plants is identical.

Direct contact with the plant is unnecessary for the rash to occur. Highly sensitive persons may develop severe dermatitis merely from exposure to Rhus oleoresin carried by pollen or by smoke from burning leaves. The oleoresin may remain active for months on clothing, shoes, tools, and sporting equipment. Once the toxic substance is exposed to the skin, it can be spread by the hands to other areas of the body (e.g., genitals or eyes) or to people who may come into close contact with the exposed person. Although washing with soap and water may not prevent the dermatitis, even if it is done within 15 minutes of exposure, it will prevent spread of the oleoresin to other parts of the body.

Sensitive individuals should be instructed to avoid contact with the offending plant. If contact is inevitable, every effort should be made to shield exposed areas of the skin with appropriate clothing.

Exposed individuals should bathe or shower as soon as they come in from outdoors and should wash their clothes. Nonprescription topical cleansers (Tecnu, Zanfel, Mean Green Hand Scrub) claim to remove urushiol oil embedded in the skin through the action of microfine scrubbing beads and surfactants, thus possibly preventing the rash or limiting spread. They are applied to exposed areas of the skin, followed by vigorous scrubbing, and rinsed off after application.

After an initial incubation period of 5 to 21 days, a patient would be expected to react to the oleoresin in 12 to 48 hours after re-exposure. A mild exposure to these plants in a sensitized person results in a typical erythematous, vesicular, linear, and sometimes, oozing rash after 2 to 3 days; complete clearing occurs in 1 to 3 weeks.

If a large area is exposed, lesions appear within 6 to 12 hours and may appear blistered and eroded; in some cases, ulcers may appear. Healing occurs more slowly, often requiring 2 to 3 weeks for complete resolution. The following factors contribute to the development of poison ivy, poison oak, or poison sumac dermatitis: the concentration of the oleoresin to which the skin is exposed, area of exposure (i.e., the thickness of the stratum corneum), duration of exposure, site of exposure, genetic factors, and immune tolerance. It is important to determine the areas of the body that are affected. If the eyes, genital areas, mouth, respiratory tract, or more than 15% of the body is affected, the patient should receive a course of systemic corticosteroids. See Case 39-6 below.

Treatment

CASE 39-6

QUESTION 1: K.P., a 27-year-old woman, has recently returned from an outing in the woods. She now has vesicular eruptions that appear in a linear pattern on one arm and hand. She believes that she has had a poison oak reaction and requests therapy. What should be recommended at this point? What should be recommended if the condition becomes more severe?

Weeping lesions should be treated with aqueous vehicles (e.g., Burow solution or saline) as outlined in the beginning of this chapter. Lesions that are not wet or weeping should be treated with calamine lotion applied 2 to 4 times daily. The zinc oxide in calamine lotion may act as a mild astringent, although some people find this preparation to be unacceptable because of its pink color, which can stain clothes. Alternatively, a topical corticosteroid appropriate for the body part affected could be used. If K.P.'s poison oak reaction becomes more severe, additional treatment with prednisone 1 mg/kg/day for at least 2 or 3 weeks will be required; such therapy should be withdrawn slowly (1–2 weeks) to prevent recurrence of the lesions.

SYSTEMIC THERAPY

CASE 39-7

QUESTION 1: Z.T., a 19-year-old man, has just returned from a fishing trip and now has an erythematous, linear, dry eruption on his leg and arm, and a generalized eruption on his hands and face. He has been in areas that have dense poison ivy growth, and he may have burned some in the campfire. Z.T. has washed himself and his clothes thoroughly. How should he be treated?

The fact that Z.T.'s facial rash is not linear (as one would expect if he had just contacted the plant) suggests that he may have contacted the smoke of a burning poison ivy plant. This can be quite serious because the oleoresin can be carried in smoke and, if inhaled, can cause vesiculation of lung tissue leading to severe respiratory problems. Z.T. should be observed for signs of respiratory difficulties and should be treated with a course of systemic corticosteroids.

RELAPSE

CASE 39-7, QUESTION 2: Z.T.'s physician prescribed oral prednisone for his rash. He was instructed to take 80 mg/day for 14 days and to decrease the dose by 5 mg/day each day thereafter. Calamine lotion (3 times daily to affected areas) also was prescribed. After 12 days, Z.T. complains that the lesions seem to be getting worse. The lesions had cleared after 8 days of treatment, and he began rapidly tapering the prednisone at that time. Why is he experiencing a relapse?

Two weeks is the minimum course of treatment when systemic corticosteroids are used for severe cases of poison ivy, poison oak, or poison sumac. The oleoresin remains fixed in the skin, and if the systemic corticosteroid is withdrawn too soon, the lesions return. This is probably the most common reason for treatment failure with systemic corticosteroids. Alternatively, systemic corticosteroids can be discontinued before 2 weeks of treatment and a moderate-potency topical corticosteroid preparation can be started 24 hours before discontinuation of systemic corticosteroids and continued for 7 to 10 days to prevent relapse.

DRUG ERUPTIONS

Clinically recognizable adverse drug reactions are manifested on the skin more often than any other organ or organ system.[30–33] An estimated 1% to 5% of hospitalized patients experience a drug eruption.[31] Outpatient statistics are more difficult to obtain, but are probably within the same range.

Many of the common dermatologic reactions that can be induced by drugs have other causes as well, so a complete workup must include other nondrug etiologies. Viral, fungal, and bacterial infections, as well as certain systemic diseases and foods, have been identified as causes for common reactions such as urticaria, erythema multiforme, and erythema nodosum. The diagnosis of drug eruptions is best made by identifying the type of lesions observed and associating the lesions with specific drug therapy. The most important diagnostic criterion is an accurate assessment of the skin lesions. With this critical information, the clinician can then refer to a drug information source to associate any current or past drug therapy with the specific lesions observed (see Chapter 32, Drug Hypersensitivity Reactions).

Acneiform Eruptions

Acneiform eruptions appear very much like common acne. They may be distinguished from acne by their sudden occurrence, the absence of comedones, uniform appearance (i.e., all at the same stage of development), and the fact that they may occur on any part of the body. Cysts and scarring are rarely associated with drug-induced acne. Eruptions can also occur during any period of the patient's life; thus, drug-induced acne should be suspected when the lesions appear in persons outside the typical age bracket for acne. Drugs implicated include adrenocorticotropic hormone, anabolic steroids, azathioprine, danazol, glucocorticoids, iodides, bromides, lithium, gefitinib, erlotinib. lapatinib, and oral contraceptives. For patients with acne vulgaris, these drugs may worsen existing lesions (see Chapter 40, Acne).

Photosensitivity Reactions

Photosensitivity eruptions require the presence of both a drug (or chemical) and a light source of appropriate wavelength. These eruptions are divided into two subtypes: phototoxic and photoallergic. Phototoxic reactions, the most common drug-induced photodermatosis, manifest themselves as an exaggerated sunburn or increased sensitivity to sunburn. The ultraviolet A (UVA) light source alters the drug to a toxic form, resulting in tissue damage independent of any allergic response, and occurs in everyone who gets high enough skin levels of the offending drug. This eruption can occur on first exposure to a drug, is dose-related, and will continue as long as the skin concentration of the drug exceeds the threshold level for the reaction to occur. Photoallergic reactions, which are very uncommon, may appear as a variety of lesions, including urticaria, bullae, and eczema. UVA light alters the drug so it becomes an antigen or acts as a hapten. Photoallergic eruptions require previous contact with the offending drug, are not dose related, exhibit cross-sensitivity with chemically related compounds, and are secondary to the use of topical agents. Unfortunately, outside light through a window and fluorescent lighting permit passage of or can emit UVA light. In addition, until recently there were inadequate topical preparations that provide protection against UVA light. Avobenzone, although covering much of the UVA spectrum, is photolabile, losing 60% of its effectiveness in less than 1 hour. However, many products now solve that problem by adding agents such as octocrylene, which stabilize avobenzone's photolability, and are usually labeled "stabilized UVA protection." New products containing ecamsule appear to offer an advance in protection against lower spectrum UVA rays. Most phototoxic and photoallergic reactions occur fairly soon after exposure to light. Implicated drugs are numerous, including among others, antibiotics (tetracyclines, fluoroquinolones, and sulfonamides), antidepressants (tricyclics), antihypertensives (hydrochlorothiazide, β-blockers), hypoglycemics (sulfonylureas), nonsteroidal anti-inflammatory drugs, sunscreens (p-aminobenzoic acid [PABA]),

---

oral contraceptives, and antipsychotics (phenothiazines) (see Chapter 42, Photosensitivity, Photoaging, and Burns Injuries).

Allergic Contact Dermatitis

Topical administration of a sensitizing agent produces localized papulovesicular lesions. These lesions are limited only to areas that are exposed to the topical product. Neomycin, benzocaine, and diphenhydramine are well-known topical sensitizers (Table 39-11).[34–36] Systemic administration of a drug to a patient previously sensitized to the drug by topical application can provoke widespread dermatitis. Implicated systemically or topically administered drugs that reactivate allergic contact dermatitis include procaine or benzocaine, radiographic contrast media or iodine, and streptomycin and gentamicin or neomycin, among others.

Erythema Multiforme

As the name implies, erythema multiforme (EM) eruptions take on a varied spectrum of morphologic forms, ranging from the mildest with tiny maculovesicular lesions to more severe forms such as SJS and toxic epidermal necrolysis syndrome (TENS) with extensive bullous lesions and routine involvement of mucous membranes. Although all forms have been reported to have oral lesions, they are much more severe in SJS and TENS, in which genital, nasal, and ocular mucosae can also be involved. Target lesions are usually present in all forms of the disorder, which characteristically are erythematous, iris-shaped papules, and vesiculobullous lesions typically involving the extremities, especially the palms and soles in EM and the torso in SJS and TENS. The lesions take on the appearance of a circular target with a bull's-eye in the middle, thus the term target lesion. Questions have recently been raised about the shared pathologic nature of these forms of EM.[37] EM in its mildest forms, EM minor and EM major, is more common in children and young adults, and is self-limited in nature with only transient hypopigmentation or hyperpigmentation as complications. Sometimes malaise, a low-grade fever, and itching or burning may accompany this type of eruption. Etiologic factors associated with EM include drugs, mycoplasma and herpes infections, radiation therapy, foods, and sometimes neoplasms. Allopurinol, barbiturates, phenothiazine, and sulfonamides are the drugs most often implicated in EM eruptions.

Table 39-11

Frequent Contact Sensitizers

Substance	Found In
Ammonia	Soaps, chemicals, hair dyes

Antihistamines	Topical anti-itch creams and ointments
Balsam of Peru	Cosmetics
Benzyl alcohol	Medications, cosmetics
“Caine” anesthetics	Medications (e.g., over-the-counter benzocaine products)
Carba	Rubber
Chromium	Jewelry
Epoxy resin	Glue
Ethylenediamine	Stabilizer in topical products (e.g., aminophylline)
Formaldehyde	Shoes, clothing, soaps, insulations
Mercaptobenzothiazole	Rubber
Naphthyl	Rubber
Neomycin	Topical medications (e.g., Neosporin)
Nickel sulfate	Jewelry, fasteners
Paraben	Preservative in many topical products
Paraphenylenediamine	Hair dyes, leather
Potassium dichromate	Shoes, leather
Thiomersal	Preservatives, contact lens products
Thiram	Rubber products
Turpentine	Paint products
Wool alcohols	Lanolin-containing products, clothes

Stevens–Johnson Syndrome

SJS is probably the most common type of severe drug eruption. The syndrome is usually a moderate mucocutaneous and systemic reaction. Blisters and atypical target lesions involve less than 10% of body surface area, with some epidermal detachment, which can cause scarring in some cases.

With more extensive involvement, clinical findings are almost indistinguishable from TENS. The skin can become hemorrhagic, and pneumonia and joint pains may occur. Serious ocular involvement is common and can culminate in partial or complete blindness. Besides drugs, this syndrome has been associated with infections, pregnancy, foods, deep radiographic therapy, and neoplasms. Mortality is estimated to be in the range of 5% to 18%. The duration of the syndrome is usually 4 to 6 weeks. The long-acting sulfonamides are most often implicated. Allopurinol, carbamazepine, fluoroquinolones, hydantoin, phenylbutazone, piroxicam, and other sulfa derivatives such as sulfonylureas are also possible causative agents.

Toxic Epidermal Necrolysis Syndrome

Epidermal necrolysis, a severe, life-threatening mucocutaneous and systemic reaction, may be preceded by a prodrome characterized by malaise, lethargy, fever, and occasionally throat or mucous membrane soreness. Epidermal changes follow and consist of erythema and massive bullae formations that easily rupture and peel, giving the skin a scalded appearance.

Hairy parts of the body are usually not affected, but mucous membrane involvement is common. Blisters cover more than 30% of body surface area, with extensive epidermal detachment that can result in scarring. Mortality in TENS patients is roughly 30%, often within 8 days after bullae appear. The usual cause of death is infection complicated by massive fluid and electrolyte loss, similar to patients with extensive burns. Although the skin takes on a grave appearance, healing occurs within 2 weeks in approximately 70% of patients, with some potential for scarring. In addition to drugs, certain bacterial infections and foods are believed to cause this type of eruption. Most causes of TENS in children are owing to infection (e.g., S. aureus). A higher incidence of this type of drug eruption appears to occur in HIV-positive patients. Drugs most frequently implicated include allopurinol, aminopenicillins, carbamazepine, hydantoin, phenylbutazone, piroxicam, and sulfa drugs.

Erythema Nodosum

Erythema nodosum eruptions appear as red, indurated, inflammatory nodules on the shins and knees.v

In addition to the unusual distribution, the lesions are tender when palpated. Occasionally, these lesions are accompanied by mild constitutional symptoms, but there is usually no mucous membrane involvement. Etiologic factors associated with the development of erythema nodosum include drugs, female sex, rheumatic fever, sarcoidosis, leprosy, certain bacterial infections (e.g., tuberculosis), and systemic fungal infections such as coccidioidomycosis. Usually, the lesions heal slowly over the course of several weeks after the offending agent is removed. Oral contraceptives are the most frequently implicated drug with this type of eruption. Other implicated drugs include sulfonamides and penicillin.

Drug Hypersensitivity Syndrome

This severe systemic reaction is also known as anticonvulsant hypersensitivity syndrome and as a drug reaction with eosinophilia and systemic symptoms (DRESS). Symptoms begin with a high fever followed by widespread maculopapular–pustular rash on the trunk, arms, and legs that may lead to exfoliative dermatitis with large areas of skin sloughing. Hair and nails are sometimes lost. Eosinophilia occurs in greater than 50% of cases, 30% have abnormal lymphocytosis, and 20% have lymphadenopathy. Internal organ damage appears late in the syndrome with elevations of liver function or renal function laboratory values. These may be accompanied by other general systemic symptoms such as headache and malaise. Secondary bacterial infections can occur. Approximately 10% of patients die, many because of infection. If exfoliative dermatitis occurs, it can take weeks or months to resolve, even after withdrawal of the offending agent. The most commonly implicated drugs are sulfonamides, antimalarials, anticonvulsants, and penicillin. Although rarely reported in the literature, its broad range of symptoms, confusing nomenclature, and symptom overlap with other drug-related adverse effects may lead to underdiagnosis and reporting.

Maculopapular Eruptions

Maculopapular eruptions are subdivided into two groups: scarlatiniform and morbilliform. Most drug eruptions fall within one of these two groups. Scarlatiniform eruptions are erythematous and usually involve extensive areas of the body. They are differentiated from streptococcal-induced scarlet fever by the lack of other diagnostic signs and laboratory studies. Morbilliform eruptions usually begin as discrete, reddish-brown maculae that may coalesce to form a diffuse rash. These eruptions are differentiated from measles by the lack of fever and other typical clinical signs. In either type of maculopapular eruption, pruritus may or may not be present. Generally, this type of eruption appears within 1 week after the causative drug (2 or more weeks with penicillins) has been started and completely clears within 7 to 14 days after stopping it. Morbilliform eruptions commonly are caused by ampicillin, amoxicillin, and allopurinol.

Urticaria

Urticarial eruptions are immediate hypersensitivity reactions (IgE-mediated) and usually appear as sharply circumscribed (raised), edematous, and erythematous lesions (wheals) with an abrupt onset.

In most cases, individual lesions disappear within 24 hours. These are replaced with new lesions elsewhere until the offending allergen is cleared from the body. Urticarial lesions are associated with an intense itching, stinging, or prickling sensation. Commonly called hives, urticarial eruptions are frequently associated with certain drugs, foods, psychic upsets, and serum sickness. The most frequently implicated drugs with this type of reaction are aspirin, penicillin, and blood products. Patients who exhibit urticaria attributable to a drug are at increased risk of anaphylaxis if re-exposed to the same medication in the future.

Angioneurotic Edema

Angioneurotic edema (also called angioedema) is a more severe form of urticaria in which giant hives penetrate more deeply into surrounding tissues.

Lips, mouth, tongue, and eyelids are common locations. Extensive involvement of the tongue, throat, or larynx can be fatal.

Angiotensin-converting enzyme inhibitors (ACEIs) are the most common drug cause of angioedema. Patients taking ACEIs should be warned to look out for any unusual swelling in the facial or oral area and, if present, should go immediately to the nearest emergency room for treatment. Although it usually occurs within the first several months of treatment, cases have been reported up to as long as 3 years after initiation of ACEI therapy (see Chapter 14, Heart Failure and Chapter 32, Drug Hypersensitivity Reactions).

CASE 39-8

QUESTION 1: D.Z., a 42-year-old man with a chronic seizure disorder and long-standing anxiety, was recently given a prescription for penicillin V 250 mg 4 times daily for a group A, α-hemolytic streptococcal-positive pharyngitis. Chronic medications include carbamazepine 200 mg 3 times daily and clonazepam 2 mg 2 times daily. One week later, D.Z. presents with urticarial lesions on his chest and arms. Is this a typical time of onset for a drug-induced dermatologic reaction? How should the drug eruption in D.Z. be managed?

Although most drug eruptions occur within 1 to 2 weeks after starting therapy, it may take 3 to 4 weeks after an initial exposure to a medication for the reaction to occur. Repeated exposure to the same offending agent can reduce the time of onset of the reaction to a few days or even within hours of ingestion. Because D.Z. has been taking clonazepam and carbamazepine chronically and penicillin for only 8 days, the temporal relationship would logically lead to the conclusion that penicillin is a highly probable cause. Almost all cases of urticaria are associated with extensive eosinophilia; however, it is not specific for any particular antigen. However, before labeling penicillin as the cause of his drug eruption, a thorough history to rule out other common nondrug causes should be taken.

For D.Z., a different antibiotic (macrolide) should be substituted for penicillin (to complete the 10-day course of therapy). The individual lesions should begin to clear in 24 hours of eruption (if the penicillin is the cause of the urticaria). If the urticaria does not begin to clear in a few days, another cause should be investigated.

Treatment is primarily supportive, and use of an oral antihistamine (e.g., diphenhydramine 25–50 mg 4 times daily) for several days would be recommended. If the reaction is severe, a 1- to 2-week course of prednisone 40 to 60 mg/day will control most symptoms within 48 hours.

Acne

Jamie J. Cavanaugh and Kelly A. Mullican

CORE PRINCIPLES

		CHAPTER CASES
1	Acne is a condition in which the pilosebaceous units of the skin become plugged and distended, presenting as comedones, papules, pustules, or nodules.	Case 40-1 (Questions 1, 2), Case 40-3 (Question 1), Case 40-4 (Question 1), Case 40-5(Question 1)
2	Drug therapies work by reducing sebum production, normalizing keratinization in the pilosebaceous units, reducing Propionibacterium acnes, or reducing inflammation.	Case 40-1 (Questions 1, 2), Case 40-3 (Question 1), Case 40-4 (Question 1), Case 40-5(Question 1)
3	Patients must be counseled that pharmacotherapy works best to prevent future lesions, not to resolve current ones. Therefore, topical therapies should be applied regularly to the entire acne-prone area(s), not just to lesions. Full treatment effect takes time from weeks to months for most treatment options.	Case 40-1 (Question 3), Case 40-2 (Question 1)
4	Appropriate choice of vehicle ensures efficacy and tolerability of topical therapy. Gels should be used in patients with normal to oily skin, and lotions and creams should be reserved for those with dryer skin types.	Case 40-1 (Question 4), Case 40-3 (Question 2)
5	Topical retinoids are first-line monotherapy for comedonal acne. They are also key components of combination therapies in maculopustular acne and preferred agents to continue for maintenance therapy once acne is under control. If comedonal acne cannot be controlled with topical retinoids alone, then salicylic acid or azelaic acid may be used as adjunctive therapy.	Case 40-1 (Questions 2, 3), Case 40-2 (Question 1), Table 40-1
6	Initial treatment for maculopustular acne is a topical retinoid in combination with topical or oral antibiotics. If treatment with topical antibiotics is selected, the regimen should also include topical benzoyl peroxide to reduce the development of antibiotic resistance. Antibiotic duration should be limited to the period needed to obtain control of acne; then the retinoid, with or without benzoyl peroxide, should be continued as maintenance therapy.	Case 40-3 (Questions 1, 2), Table 40-1
7	Antiandrogenic therapies, such as combined oral contraceptives or spironolactone, are useful alternative treatment options for maculopustular acne in nonpregnant women.	Case 40-4 (Question 1), Table 40-1
8	Oral isotretinoin monotherapy should be used to treat nodular acne.	Case 40-5 (Questions 1–6),

Isotretinoin is extremely effective and can induce a lengthy remission of acne, but the adverse effect profile and the need for laboratory monitoring preclude use in comedonal or maculopustular acne. The iPLEDGE risk management program controls isotretinoin distribution to prevent accidental prescription of this severe teratogen to pregnant women.

Table 40-1

DEFINITION AND EPIDEMIOLOGY

Zits, pimples, whiteheads, and blackheads are all terms commonly used for acne vulgaris, or simply acne. Acne is a condition in which the pilosebaceous units of the skin become plugged and distended, presenting as comedones, papules, pustules, or nodules. Unless otherwise stated, all references to acne in this chapter refer to acne vulgaris.

Acne affects an estimated 9.4% of the world population, including greater than 90% of all adolescents in the United States.[1,2] While teenagers and young adults are typically afflicted by acne, it can occur at any age. Acne often begins when sebaceous gland activity increases in association with puberty. Because the onset of puberty has decreased in recent years, so has the age of acne onset. Acne is now seen as early as 8 to 9 years of age, with peak onset occurring between 16 and 20 years.[3,4] Acne tends to dissipate in most patients by their 30s; however, up to 20% of the patients have acne persisting into adulthood.[5] There is no known cure for acne, but treatment can reduce its severity and minimize scarring.

PATHOPHYSIOLOGY

There are four primary mechanisms responsible for acne: (1) increased sebum production, (2) hyperkeratinization, (3) colonization of Propionibacterium acnes (P. acnes), and (4) release of inflammatory mediators to the skin. Acne begins with the overproduction of sebum, often secondary to an increase in androgen levels.

Androgens such as dehydroepiandrosterone sulfate (DHEAS) are metabolized to dihydrotestosterone (DHT) in the skin, which in turn stimulates sebum biosynthesis. DHEAS levels rise before puberty and begin to decline in early adulthood.[6] An increase in sebum production triggers keratinization which is the proliferation of keratinocytes in the follicular epithelial lining. Keratinization increases cell-to-cell adhesion, interfering with normal desquamation. The cellular debris from keratinization, in addition to excess sebum accumulation, causes sebaceous follicles to plug and form undetectable microcomedones. If the superficial portion of the follicular opening dilates from the pressure of the impaction, an open comedo (blackhead) forms. The dark color of open comedones is caused by light refraction, not by dirt; comedo contents are white when expressed.[7] Such lesions rarely become further inflamed, because as pressure builds from further sebum production and cellular accumulation, follicular contents can escape to the skin surface.[8] If the follicular opening remains narrow and a closed comedo (whitehead) forms, increased pressure can rupture the follicular wall, with infiltration of foreign matter into the dermis inciting a marked local inflammatory response. The depth and extent of this occurrence determine whether a papule, pustule, or nodule results.[9]

Distension in the follicle and increased sebum production allow the gram-positive anaerobe, P. acnes, to colonize and proliferate. The occupation of P. acnes in the follicle stimulates the upregulation of cytokines and releases proteases, hyaluronidases, lipases, and chemotactic factors that attract neutrophils, T cells, and macrophages.[10] Hydrolytic enzymes released by macrophages may contribute to weakening of the follicular wall, hastening rupture, and resulting progression of comedo to inflammatory lesion.[8] Inflammatory mediators traverse the follicular wall into the dermis and intensify the inflammatory process even before wall rupture.[7]

CLINICAL PRESENTATION

Acne presents as comedones or inflammatory papules, pustules, or nodules. (See Chapter 39, Dermatotherapy and Drug-Induced Skin Disorders.) In severe cases (acne conglobata), multiple lesions coalesce into abscesses with draining sinus tracts. Acne lesions generally appear in areas with the highest density of pilosebaceous units including the face, neck, upper chest, shoulders, and back.[11]

Sunlight and diet may be risk factors for worsening acne, but are controversial.[11] Ultraviolet light may make sebum more comedogenic, but some of the visible wavelengths may reduce the follicular bacterial population.[12] As for diet, studies have investigated lower-milk-intake and lower-glycemic-load diets for potential benefit in acne,[13] but research on dietary modifications is not yet sufficiently robust to alter routine patient care.

Risk factors for acne include a family history and increased body mass index. Worsening of acne has been associated with times of increased stress.[11]

DIAGNOSIS

The differential diagnosis of acneiform eruptions includes (a) acne vulgaris, (b) rosacea, (c) folliculitis caused by gram-negative bacteria, Pityrosporum, or mechanical irritation, (d) drug-induced acne (acne medicamentosa) such as that caused by topical or systemic corticosteroids, or by anabolic steroids, and (e) perioral dermatitis.[9,14] Detailed discussions of severe acne variants, such as acne conglobata and acne fulminans, are beyond the scope of this chapter. In addition, acne may be secondary to systemic diseases, such as SAPHO (synovitis, acne, pustulosis, hyperostosis, osteitis) and Apert syndromes.[15]

There is no standard for the grading of acne severity. Initial treatment should be selected based on patient-specific factors including the presence of comedonal, maculopustular and nodular acne, which are used in order to guide treatment decisions. Clinicians may choose to adopt an acne severity scale to assist in the assessment of therapy.[16]

OVERVIEW OF THERAPY

Treatment is individualized and depends on the clinical presentation of the patient. The goals of the treatment are to relieve discomfort, improve skin appearance, prevent scarring, and minimize the psychosocial impact of the condition.

Treatment is largely preventive because little can be done for existing lesions. Slow improvement over the course of weeks to months is expected for all treatments. Therefore, treatment regimens should not be modified more often than every 6 to 8 weeks. Although some acne may resolve without residual changes, it is important to counsel patients that inflammatory acne may result in scaring or hyperpigmentation, which, while reversible, may take several months to fully resolve. Recognition of the duration of improvement of these secondary symptoms is important when considering the efficacy of a medication because patients may not recognize the improvement.[17] Patients should be counseled on the basic pathophysiology of acne, proper drug administration or application technique, delay in onset of therapeutic effect, potential adverse effects of any recommended therapy, and steps to take if adverse effects occur. Clinical practice guidelines are available. Table 40-1 outlines a general approach to the treatment of acne.[10,16,18]

Nonpharmacologic Therapy

Nonpharmacologic therapy plays a minimal role in the management of acne. There is no good evidence to support that acne can be caused or cured by poor hygiene. Twice-daily washing with warm water and mild facial cleanser may suffice; however, excessive washing and scrubbing should be avoided. Using harsh cleaners disrupts the skin barrier encouraging bacterial colonization and the removal of oil from the skin, which further stimulates its production.[17] To minimize scarring, patients must resist squeezing or picking at acne lesions. Drugs known to cause acne, such as corticosteroids, androgens, and anabolic steroids, should be avoided when possible.[19] In addition, oil-based cosmetics and other known precipitants should be avoided. Oil-free, noncomedogenic moisturizers formulated for facial skin can improve the penetration and tolerability of many topical acne drugs by improving the skin's hydration, especially in patients with sensitive skin.

Table 40-1

Treatment Selection by Acne Type

Type	Treatment Options
Comedonal acne	Topical retinoid, azelaic acid Or Salicylic acid
Maculopapular acne	Topical retinoid + topical antimicrobial (antibiotic or benzoyl peroxide) Or Topical retinoid + oral antibiotic + benzoyl peroxide Or (additional options for female patients) Combination oral contraceptive Androgen receptor antagonist
Nodular acne	Isotretinoin

Dermatologists may use procedures such as surgical comedo extraction, chemical peels, and microdermabrasion as adjunct therapy to improve cosmetic appearance. Current guidelines prefer drug therapy to light and laser therapies because there are less stringent clinical testing for devices versus drugs, concern about long-term effects of therapies aimed at sebaceous gland function, and the inadequate research done on light and laser therapies to date.[10] Acne scarring is treated with various microsurgical techniques such as dermabrasion, laser therapy, chemical peels, and tissue augmentation.[20]

Pharmacotherapy

Available drug therapies exhibit one or more of the following mechanisms: (a) normalizing follicular keratinization (e.g., retinoids, benzoyl peroxide to some degree, azelaic acid); (b) decreasing sebum production (e.g., isotretinoin, hormonal therapies); (c) suppressing P. acnes (e.g., antibiotics, benzoyl peroxide, azelaic acid, systemic isotretinoin); and (d) reducing inflammation (e.g., antibiotics, retinoids).

COMEDONAL ACNE CASE

CASE 40-1

QUESTION 1: L.Y. is a 15-year-old female who presents to the pharmacy asking for the best way to treat her "zits." The problem started earlier this year around the same time that she joined the track team. Upon examination, you can see several closed comedones on her nose and chin and open comedones dispersed across her forehead covered by makeup. Her skin is slightly oily, and you can see that she is wearing a sweatband around her head. She would like to know what you recommend to get rid of her "zits." What factors could be contributing to her acne?

There are several factors that may be contributing to L.Y.'s acne. Mechanical irritation caused by the sweatband may cause acne mechanica. Increased sweat and humid conditions encountered while running track can lead to favorable conditions for the colonization of P. acnes. Finally, it is important to ask L.Y. whether her makeup is oil based, because oil-based products can be comedogenic.

Pharmacotherapy

CASE 40-1, QUESTION 2: What are the treatment options for L.Y.'s acne?

Topical therapies are the most appropriate first-line treatment for comedonal acne. Options include retinoids, azelaic acid, and salicylic acid.

TOPICAL RETINOIDS

Retinoids, analogs of vitamin A, normalize keratinization by decreasing horny cell cohesiveness and stimulating epidermal cell turnover. These actions combine to unplug follicles and prevent microcomedo formation. Retinoids reduce inflammation by inhibiting the production of inflammatory mediators. It is important to note that topical retinoids have no antibacterial properties.[21]

As the most potent comedolytic agents, topical retinoids are preferred therapy in comedonal acne.[18] They are also a core component of combination therapies for maculopapular/pustule acne and a first-line treatment to maintain remission of acne once it is controlled. Tretinoin, all-trans-retinoic acid, is the naturally occurring form of vitamin A acid and is a first-generation topical retinoid. It is generally well tolerated, although it can cause retinoid dermatitis leading to further hyperpigmentation if used too aggressively in patients with darker skin tones. Starting at a low dose or using creams over gels can minimize the risk of worsening hyperpigmentation.[22] Alternatively, adapalene, a retinoid-like product, that binds to specific retinoic acid nuclear receptors can be used. It is generally well tolerated and, in addition to decreasing risk for hyperpigmentation, has a greater anti-inflammatory effect than tretinoin. Tazarotene is a second-generation topical retinoid available and, although effective, is the least tolerated agent in this class.[23]

Topical retinoids and retinoid-like products should be applied once daily at bedtime to avoid degradation in ultraviolet light.[24] Common adverse effects of this class include skin irritation, peeling, erythema, and dryness.[23] The irritation potential depends on the drug concentration and vehicle used. Patients should be counseled to apply daily sunscreen and gentle moisturizing cream while using these agents.[24] Patients should be aware that acne might initially worsen during treatment because pustular flares can occur.

AZELAIC ACID

Azelaic acid is a dicarboxylic acid that works to normalize keratinization and indirectly reduces inflammation through suppression of P. acnes.[25] Formulations in the 20% strength are indicated for the treatment of acne, whereas the 15% gel, Finacea, is indicated for rosacea. Although azelaic acid hits several of the pathways leading to acne formation, the evidence for use is not as robust as other topical agents.[21] It is applied twice daily to the skin and could be an option for patients who are unable to tolerate other topical therapies.

SALICYLIC ACID

Topical salicylic acid works as a concentration-dependent keratolytic agent. It is commonly reserved for patients with comedonal acne who cannot tolerate other comedolytic therapies or as augmentation to other therapies as studies have demonstrated that their effectiveness is less than either topical retinoids or benzoyl peroxide.[26] It is typically applied twice daily and is not effective if soly used as needed. Patients should be cautioned regarding chronic use over large body surfaces because it increases the risk of percutaneous absorption that could lead to systemic salicylate toxicity.[27]

CASE 40-1, QUESTION 3: What treatment option is most appropriate for L.Y.?

Topical retinoids are first-line agents for her type of acne. Selection of the specific topical retinoid is provider-specific and generally depends on what is most affordable for the patient. Adapalene should be considered for patients with darker skin tones secondary to the reduced risk for hyperpigmentation. She should be instructed to apply the product to her entire face every other day for the first 2 weeks and then advance to daily as tolerated. It is important to let L.Y. know that this is for routine and not as needed use in order to be effective and that she will need to wait several weeks before judging its effectiveness. She should apply the product at bedtime, ideally 30 minutes after washing her face with a mild cleanser, and wash it off in the morning (or after several hours, if excessive skin dryness or peeling occurs).

CASE 40-1, QUESTION 4: What vehicle would you recommend for L.Y.?

L.Y. has slightly oily skin. Therefore using a gel is the vehicle of choice because it has more drying effects compared to lotions of creams.

CASE 40-2

QUESTION 1: M.G. is a 27-year-old female who presents to the dermatology clinic with open and closed comedones spread across her cheeks and forehead. She was recently prescribed adapalene 0.1% lotion, which she has been applying daily for the last 6 months without much success. She is not sure what else she can do to manage her acne. What would you recommend M.G. to better manage her acne?

Although topical retinoids are first-line treatment for comedonal acne, some patients require additional agents to achieve satisfactory results. M.G. should be instructed to continue adapalene and initiate salicylic acid wash daily. This wash should be used on her entire face, not just areas with active breakouts, twice daily. It is important to remind her that it may take several weeks before she sees an effect.

MACULOPAPULAR ACNE

Pharmacotherapy

ANTIBIOTICS

Although P. acnes is part of the skin's normal flora, under the conditions leading to acne, it helps transform comedones into inflammatory pustules or papules. Antibiotics do not resolve existing lesions, but they can prevent future lesions by decreasing both P. acnes colonization and inflammation. The antibiotics that are most effective in acne have antioxidant properties. In addition, antibiotics inhibit the release of reactive oxygen species by P. acnes, which in turn reduces leukocyte recruitment.[10] Due to this multifactorial mechanism of action, clinical efficacy does not correlate perfectly with reductions in bacterial load; successful antibiotic courses do not necessarily eradicate P. acnes.[28]

Topical Antibiotics

Topically applied antibiotics avoid systemic exposure and achieve high follicular concentrations. They can augment topical retinoids when initiating therapy for comedonal and papular acne cases involving inflammatory lesions, or they can be added to regimens for patients failing monotherapy. Topical antibiotics alone in acne treatment should be avoided due to concerns for bacterial resistance.[21]

Topical antibiotics are usually applied once or twice daily for 3 months. Although rare reports of systemic adverse effects exist, topical effects, such as stinging and tingling, are the most common adverse effects, and even these occur less frequently with topical antibiotics compared to other topical therapies.

Doxycycline is most convenient and effective; tetracycline is an alternative.[29] Tetracyclines should not be prescribed for children younger than 9 years of age because of potential impairment of bone growth and discoloration of forming teeth. Pregnant women must avoid tetracyclines because of bone growth effects on the fetus. Minocycline is sometimes tried if other tetracyclines fail, but is more expensive and not clearly better in efficacy, even in resistant acne. It is also associated with a higher rate of serious adverse effects than other tetracycline antibiotics.[30]

Trimethoprim/sulfamethoxazole is also effective, but has a less favorable adverse effect profile when compared to tetracycline. It is reserved for situations when other antibiotics are unable to be used.[16] In patients who are unable to take oral antibiotics mentioned above (including pregnant patients), erythromycin may be an option despite association with higher rates of resistance.

Most oral antibiotics are given twice daily for a 3-month course, followed by continuation of a topical retinoid for maintenance therapy.[23]

Oral Antibiotics

Oral antibiotics should not be used as monotherapy. Benzoyl peroxide may be added for patients with maculopustular or nodule acne. If lesions are widespread or difficult to reach, oral antibiotics are generally preferred over topical agents. They are also used as a step-up therapy when topical antibiotic regimens fail to suppress acne.

Antibiotic Resistance

Antibiotic resistance of P. acnes is increasing and correlates with prescribing patterns. Erythromycin has the highest rate of resistance. Resistance to tetracyclines is less common and is increasing at a slower rate than resistance to other antibiotics. In an effort to minimize resistance, guidelines increasingly emphasize that antibiotics should be reserved for acne of at least maculopapular subtype. Antibiotics should be used with drugs exerting additional mechanisms of action, ideally topical retinoids, rather than used as monotherapy, and should be used for the shortest effective duration to obtain acne control (trials to stop antibiotics every 3 months). Antibiotics should not be used for maintenance of control (rather, the retinoid should be continued for maintenance). Including benzoyl peroxide in regimens containing antibiotics reduces the development of resistance, and it is particularly recommended if antibiotic therapy needs to be continued beyond 3 months to maintain control.[21] If adherence to therapy with an antibiotic and both topical retinoid and leave-on benzoyl peroxide formulations is challenging, even a benzoyl peroxide wash product can be helpful.[31,32] Dual antibiotic use is inappropriate because it increases the risk of bacterial resistance without offering therapeutic gain, as bacterial eradication is not a therapeutic goal.

BENZOYL PEROXIDE

Benzoyl peroxide is another effective agent for those with maculopustular acne. It works through three mechanisms: antimicrobial, anti-inflammatory, and keratolytic effects. It is important to note that there is no reported resistance of P. acnes to benzoyl peroxide. Benzoyl peroxide is available over-the-counter and by prescription in a variety of dosage forms. It is important to be aware that benzoyl peroxide inactivates some formulations of tretinoin, so they should not be used together, or should at least be applied at different times (morning and evening, respectively).[33] However, benzoyl peroxide can be used in combination with either adapalene or tazarotene to provide additive benefit. Benzoyl peroxide is usually applied to the affected area once or twice daily. The most common adverse effects of benzoyl peroxide include contact dermatitis (occurs in up to 2.5% of patients), erythema, peeling, and skin drying.[27] Those who develop contact dermatitis should be instructed to stop. Patients should be counseled to be careful when applying this medication because it can bleach hair and dyed fabrics.

CASE 40-3

QUESTION 1: R.P. is an 18-year-old male who has had acne since his early teens. He started out with comedonal acne alone, but now has a number of inflammatory pustules across his forehead and nose. Upon further examination, you can also see that he has dry skin with numerous comedones on his chin. R.P. was prescribed tretinoin 0.1% gel in the past, but he stopped this due to skin irritation and dryness. He has been using salicylic acid washes daily, without success. What changes to R.P.'s medication regimen do you recommend?

Guidelines currently recommend topical retinoids as a cornerstone of therapy for patients with comedonal and inflammatory acne. Although R.P. had been unable to tolerate tretinoin gel in the past, it may have been secondary to the vehicle and strength of the medication that he was prescribed. Gels tend to dry out the skin and are not the preferred vehicle for patients like R.P. who have dry skin. Recommend that R.P. restarts a topical retinoid with a cream or lotion formulation. You could also recommend that he starts with a lower strength tretinoin for tolerability (available in strengths as low as 0.02%). Because R.P. also presents with pustules, he could also start on a topical antimicrobial agent such as a topical antibiotic or benzoyl peroxide.

CASE 40-3, QUESTION 2: One year later, R.P. returns to the pharmacy and reports that his acne therapy is "not working." He saw his dermatologist and has been using clindamycin lotion 1% every morning, adapalene cream 0.1% every night, and benzoyl peroxide lotion 4% daily for the past year. Upon examination, you can notice that he continues to have maculopapular acne in addition to a few nodules. What changes do you recommend to his treatment regimen?

R.P. should stop his topical antibiotic and start an oral antibiotic, such as doxycycline. If he is able to tolerate doxycycline, he should continue this medication for 6 to 8 weeks, at which point changes should be made if there is no improvement.[34,35] If the response is adequate, R.P. should try to stop doxycycline after 3 months. Topical retinoid therapy and benzoyl peroxide should be continued during doxycycline therapy and then after the antibiotic course to maintain treatment benefit. If R.P. were to experience a treatment relapse in the future, after successful use of an oral antibiotic, another course of the same antibiotic should be used; switching antibiotics offers no therapeutic benefit and can promote multidrug resistance.[31] With only a few nodules present, it is not appropriate to initiate oral isotretinoin without adequate trials of other treatment options.

CASE 40-4

QUESTION 1: M.J. is a 24-year-old female who presents to the clinic with maculopapular acne. She reports that her acne typically worsens 1 week before her menstrual cycle and improves once menses begins. She says that she is tired of applying all of these creams and is looking for an alternative way to manage her acne. What treatment options would you recommend for her?

HORMONAL THERAPIES

Hormonal therapies with antiandrogenic effects, such as androgen receptor antagonists and combination oral contraceptives, are the only treatments besides oral isotretinoin to attack acne by reducing sebum production. Hormonal therapies may be helpful in patients with normal serum androgen levels, as well as in patients with elevated serum androgen levels, because hypersensitivity to androgens sometimes occurs at the follicular level despite normal circulating androgen levels.[32] These treatments are good options for women with acne who are not pregnant, for those who desire contraception, and for women with polycystic ovary syndrome or other hyperandrogenic conditions or symptoms.[32] Systemic effects of hormonal therapy generally preclude their use in male patients. Response to hormonal therapies can take 3 to 6 months because their mechanism of action, reducing sebum production, is an early step in the cascade of acne pathology.[36]

Androgen Receptor Antagonists

Spironolactone at doses of 25 to 100 mg/day reduces acne because it is an androgen receptor antagonist and inhibits 5-β-reductase. Tolerability and serum potassium should be monitored every 3 weeks until maximum tolerated dose or 100 mg/day is achieved, titrating in 25-mg increments. Spironolactone is generally well tolerated, although gynecomastia, menstrual irregularities, and hyperkalemia are possible.[32] Female patients should use contraception because of the potential for antiandrogen exposure to impair the sexual development of male fetuses. Spironolactone should be used with caution in male patients given the risk for gynecomastia and possibly lower efficacy when compared to female patients.[37]

Combination Oral Contraceptives

Estrogen, usually administered as ethinyl estradiol in a combination oral contraceptive, improves acne in females by reducing ovarian androgen production and by increasing sex hormone-binding globulin concentrations in the serum, thereby lowering free testosterone levels. The manufacturers of Ortho Tri-Cyclen, Gianvi, Loryna, Nikki, Vestura, Estrostep, and Yaz specifically sought and obtained FDA approval for acne indications. Studies of combination oral contraceptives containing levonorgestrel, norethindrone acetate, drospirenone, dienogest, nomegestrol, cyproterone acetate, desogestrel, or gestodene (not available in the United States) have demonstrated efficacy in acne.[38] Comparative trials have not yet clearly established clinically significant superiority of one product over another.[38] In individual patients, products containing progestins with androgenic effects (e.g., norgestrel, levonorgestrel) may override the effect of ethinyl estradiol and worsen acne. Conversely, patients already on a combination oral contraceptive may improve when switched to a formulation with a less androgenic progestin (norgestimate, desogestrel).[39] Other estrogen-containing contraceptives (transdermal patches, vaginal rings) may have similar beneficial effects to combination oral contraceptives, but studies have not been conducted.

If M.J. is not interested in becoming pregnant in the near future, hormonal therapy may be a good option for treatment of her acne. Because the onset of hormonal therapy is delayed, she

---

should be counseled to continue using her current treatments for at least 3 months. At that time, she may try stopping her topical treatments and continuing hormonal therapy as an acne monotherapy.

NODULAR ACNE CASE

CASE 40-5

QUESTION 1: K.S. is a 24-year-old female who first noticed acne when she was 10 years old. As a teen, she used topical benzoyl peroxide, topical adapalene, and systemic erythromycin with limited success. Two years ago, she was diagnosed with polycystic ovary syndrome and began taking Ortho Tri-Cyclen along with her maintenance adapalene treatment, after which her acne improved, but was not eradicated. Ten months ago, she also began taking minocycline 100 mg orally twice daily. After a few months, she experienced significant improvement, but she has not been able to stop antibiotics because of recurrent flare-ups. She now has at least a dozen nodules widely distributed among multiple papules and pustules on her face and back. What pharmacologic therapy would you recommend for K.S.?

Pharmacotherapy

ORAL ISOTRETINOIN

Isotretinoin (Absorica, Amnesteem, Claravis, Myorisan, Zenatane) is the only agent effective for the treatment of nodular acne largely in part due to its mechanism of action. It exhibits all four of the mechanisms of action currently used to attack acne, making it a uniquely effective monotherapy. It is administered by mouth as 10-, 20-, 30-, and 40-mg capsules. In most cases, one or two 5-month-long courses of therapy will induce a remission lasting for several months or even years after the drug is stopped. Although this medication is very effective in the suppression of acne, it is not utilized in more mild cases of acne due to its adverse effect profile. It should be reserved as a last-line therapy for patients with nodular acne and those variants of acne that are prone to scaring.

The most effective medication for K.S. will be oral isotretinoin at an initial dose of 20 mg twice daily (targeting 0.5 mg/kg/day). The dosage should be increased to 40 mg twice daily (1 mg/kg/day) as tolerated after 1 month. The dose should be divided twice daily and given with food. For best results and minimal risk of relapse, treatment should be continued until a cumulative dose of approximately 120 mg/kg is reached, usually about 5 months.[33] Higher dosages are associated with an increased risk of adverse effects. K.S. should stop taking minocycline when isotretinoin therapy begins because isotretinoin is effective monotherapy, and coadministration of isotretinoin and tetracyclines increases the risk of intracranial hypertension.[34] Adapalene is also unnecessary once isotretinoin begins. Her acne should significantly improve within the first month of therapy and gradually resolve by the third or fourth month. A second course of therapy is usually not necessary.

CASE 40-5, QUESTION 2: K.S.'s prescriber discusses enrolling her in iPLEDGE. What is the iPLEDGE program? What should K.S. know about avoiding pregnancy while taking isotretinoin?

Isotretinoin is severely teratogenic.[40] A Food and Drug Administration-mandated Risk Evaluation Mitigation Strategy (REMS) strict risk management program called iPLEDGE regulates the prescription and distribution of isotretinoin in the United States.[41] The program requires all patients, prescribers, pharmacies, and even drug wholesalers involved in distribution and use of the drug to register with a national database. Proper patient monitoring and education, including negative pregnancy tests in female patients of childbearing potential, must be documented in the database each month before initial or refill medication can be dispensed to a patient. Because of the teratogenicity or oral isotretinoin, patients (both male and female) should also be counseled not to donate blood during therapy and for at least a month after therapy, to ensure no pregnant woman receives isotretinoin-contaminated blood products.

Female patients of childbearing potential must use two forms of contraception for at least a month before, during, and a month after isotretinoin therapy. At least one contraception method must be a "primary" method. K.S. is already using an approved primary method with Ortho Tri-Cyclen; approved primary methods also include bilateral tubal ligation, partner's vasectomy, some intrauterine devices, or hormonal methods (other than progestin-only minipills). However, she must also begin using a backup method, such as condoms. The program requires that all female patients of childbearing potential must have two negative pregnancy tests before initiating isotretinoin therapy, one at the time of screening and then another, from an appropriately certified laboratory, after 1 month of using their chosen contraception regimen. The program also requires a negative pregnancy test before each monthly refill is prescribed, immediately after therapy, and a month after therapy. K.S. and her prescriber will both have to verify with the program on a monthly basis that she has been counseled again regarding contraception.

CASE 40-5, QUESTION 3: How should K.S. be counseled with regard to adverse effects of isotretinoin?

In addition to its teratogenic effects, oral isotretinoin can also cause numerous dermatologic effects including dryness, erythema, peeling and photosensitivity.[40] To minimize this, patients should be instructed to use daily moisturizers, sunscreen and protective clothing if going out into the sun. K.S. should also be counseled to avoid waxing, dermabrasions and any other dermatologic procedures during and up to 6 months after the completion of treatment. Other common side effects that K.S. should be cognizant of include hair dryness, hair thinning and nail fragility.

CASE 40-5, QUESTION 4: What laboratory testing should be performed prior to the initiation of oral isotretinoin?

Before beginning isotretinoin therapy, all patients, both male and female, should have the following baseline laboratory tests: a fasting lipid panel; a liver function panel, including both serum transaminases and bilirubin; and a complete blood count, including platelets.[40] For accurate triglyceride results, the blood sample should be collected at least 36 hours after alcohol consumption and 10 hours after having food. A lipid panel should be redrawn 4 and 8 weeks into isotretinoin therapy to document the effect of the drug because 20% of patients develop significant triglyceride elevations.[9,42] Triglyceride levels greater than 400 mg/dL should be treated with diet and reduced alcohol intake; monthly monitoring should continue throughout isotretinoin therapy. In the unusual event that triglyceride levels exceed from 700 to 800 mg/dL, isotretinoin should be discontinued, or continued at a reduced dosage with concomitant gemfibrozil therapy to reduce the risk of pancreatitis.[9] If pancreatitis develops, isotretinoin must be discontinued. Liver function tests and blood counts only need to be redrawn during therapy if symptoms suggestive of hepatitis or blood dyscrasias appear.[9,16]

CASE 40-5, QUESTION 5: K.S. has never had problems with depression, but her prescriber completed a psychiatric history and assessment of current symptoms, and her iPLEDGE patient education materials warn against possible drug-induced depression. The thought of suddenly becoming violent or suicidal concerns her. How significant is this risk?

Isotretinoin product labeling includes a warning that isotretinoin may cause depression, including suicide attempts, psychosis, and violent behavior. Case reports suggest that isotretinoin causes psychiatric symptoms in some patients. Prospective trials and literature reviews have not established a causal relationship between isotretinoin and depressive symptoms.[43] Although the absolute risk is low, drug-induced depression is a possible idiosyncratic reaction to isotretinoin in individual patients. In any case, all patients with severe acne, whether receiving isotretinoin or not, should be monitored for the development or worsening of depression.[16] K.S. should be reassured that the risk of drug-induced psychiatric symptoms is low. If she does notice any of the psychiatric symptoms listed in her medication guide, she should contact her prescriber immediately and stop isotretinoin.

CASE 40-5, QUESTION 6: After 3 weeks of therapy, K.S. complains of dry eyes, dry skin, and cracks with bleeding at the corners of her mouth. What do you recommend to manage these adverse effects?

K.S. should use artificial tears to relieve the discomfort of her dry eyes; if she is still uncomfortable after several days, she can also apply lubricating ophthalmic ointment at bedtime. She should liberally apply moisturizer to dry skin, particularly after bathing (see Chapter 39, Dermatotherapy and Drug-Induced Skin Disorders). Frequent application of a lip balm or emollient, ideally one containing sunscreen, will treat cheilitis. If the symptoms become intolerable, a small reduction in the isotretinoin dose (e.g., reduction of 10–20 mg/day) usually decreases the intensity of skin and mucous membrane reactions. Drug discontinuation is rarely necessary.[40]

Psoriasis

Jill A. Morgan, Rachel C. Long, and Timothy J. Ives

CORE PRINCIPLES	CHAPTER CASES
1 Psoriasis is a chronic, proliferative skin disease that is characterized by well-delineated, thickened erythematous skin plaques and is both topical and systemic in nature. It is immune-mediated with both vascular and inflammatory changes, which precede epidermal changes.	**Case 41-1 (Question 1)**
2 Precipitating factors for psoriasis include cold weather, anxiety and stress, viral or bacterial infections, epidermal trauma, or drugs.	**Case 41-1 (Questions 2,4)**
3 Topical corticosteroids are first-line treatment for mild psoriasis because of their prompt relief, convenience, and anti-inflammatory, immunosuppressant, and antipruritic properties.	**Case 41-1 (Question 5)**
4 Alternative topical treatments for mild psoriasis—coal tar, anthralin, calcipotriene, calcitriol, and tazarotene—and phototherapy are not as convenient as topical corticosteroids, but have well-established efficacy for initial management.	**Case 41-1 (Question 6)**
5 Treatment goals for severe psoriasis include both safe and effective resolution of the disease and long-term maintenance using agents to induce immunosuppressive or remittive cellular changes.	**Case 41-2 (Questions 1,2)**
6 Psoriatic arthritis can occur in up to 40% of patients with psoriasis, and mild disease is treated first with nonsteroidal anti-inflammatory drugs and second with an immunosuppressive agent, methotrexate.	**Case 41-3 (Question 1)**
7 Use of immunosuppressive agents can be limited as a result of adverse effects, monitoring requirements, or toxicity. There is also a lack of evidence to support that they modify the long-term disease process. Immunomodulatory therapy, including T-cell agents and TNF-α inhibitors, is thought to target the immune-mediated mechanism of psoriasis.	**Case 41-3 (Question 2)**

EPIDEMIOLOGY

Psoriasis, a chronic, proliferative skin disease, is one of the most common immune-mediated disorders, occurring in 1.5% to 3% of the population worldwide, with northern Europeans and Scandinavians affected most.[1–4] It is characterized by well-delineated, thickened erythematous epidermis or dermal plaques covered with a distinctive silvery scale. Of patients, 75% present with symptoms of psoriasis before the age of 46 years.[2] A family history of psoriasis is found in nearly half of patients. At least 36 chromosomal loci have been identified that increase psoriasis susceptibility.[5–7] Modifiable triggers, such as tobacco and alcohol use, stress, obesity, skin injury, and hormone changes, also play a major role in disease expression.[3,8]

Pathogenesis

Innate and adaptive immunity are both involved in the initiation and maintenance of psoriatic plaques. Because the epidermis is the body's main barrier to environmental insult, epidermal hyperplasia forms a key component of the innate immune response. Natural killer cells and natural killer T cells are part of the cutaneous inflammation in psoriasis.[3,9]

Because $CD4^+$ and $CD8^+$ T-lymphocytic cells constitute most of the leukocyte infiltrates found in plaques early in the development of lesions, current evidence supports an autoimmune mechanism for psoriasis. Cytokines such as interferon-α_2 or interleukin-2 are also found in psoriatic plaques.[10] T cells in the cutaneous infiltrate are positive for cutaneous lymphocyte–associated antigen, a marker for skin-homing leukocytes. Pathogenesis also involves

---

vascular and inflammatory changes, which precede epidermal changes.[11] Alterations in the dermal vasculature also appear to be a result of angiogenesis, the development of new blood vessels, similar to a number of other disease processes, including tumor growth. Many commonly used therapeutic agents for psoriasis have antiangiogenic activity.[1]

The epidermal changes of psoriasis are based on the time required for affected epidermal cells to travel to the surface and be cast off, which is markedly reduced (3–4 vs. 26–28 days in normal cells).[12] This sixfold to ninefold transit time decrease does not allow the normal events of cell maturation and keratinization to take place and is reflected clinically as diffuse scaling. T cells contribute to this keratinocyte hyperproliferation through the secretion of various growth factors.[13,14] Memory T lymphocytes marked with cutaneous lymphocyte–associated antigen, to remember the anatomic site where they first encountered antigen, migrate to the (epi)dermis by a number of immunologic and inflammatory triggering mechanisms released from keratinocytes after minor trauma. On entry into the skin, these T cells complex with epidermal self-antigens presented by major histocompatibility complex molecules that confer the risk of psoriasis. The subsequent release of T-cell cytokines results in further inflammation, the recruitment of additional marked (i.e., with cutaneous lymphocyte–associated antigen) T cells, and, ultimately, the development of psoriatic lesions in susceptible persons.[13,14]

Prognosis

Similar to those with diabetes, cancer, or heart disease, patients with psoriasis experience a reduced quality of life related to an impairment of social, psychological, and physical functioning.[15–17] Although psoriasis is a treatable disease, there is no known cure. Optimism and encouragement are justified and make it easier for patients to conscientiously apply sometimes awkward and messy topical treatments or take medications that have significant adverse effects. The goal of therapy should be to achieve complete clearing of psoriatic lesions, particularly during emotionally critical times, such as the commencement of school, puberty, and the summer months.

Clinical Presentation of Psoriasis

CASE 41-1

QUESTION 1: M.M., a 35-year-old man, presents with complaints of several thick, well-defined erythematous areas on both his elbows and knees that have silvery scales on them. He complains of itching in these areas and that the areas bleed when he removes the scales. M.M. states that he has had these lesions for some time; however, he has used over-the-counter hydrocortisone and some of his friend's triamcinolone 0.025% cream on them for the itching. He feels that the lesions have gotten worse since he went on vacation in the Dominican Republic and got "a pretty bad sunburn." His medical history is noncontributory. His only medications, besides topical corticosteroids, include a recent course of chloroquine for malaria prophylaxis during his recent travel. On physical examination, M.M. is also found to have a few scattered, circumscribed, erythematous, scaly plaques on the flexural surfaces of both arms and legs and a dense scale on his forehead and scalp. Approximately 4% of his body surface area (BSA) is estimated to be affected with psoriasis. The rest of M.M.'s physical examination and laboratory results are within normal limits.

Laboratory values and vital signs include the following:
BP, 132/78 mm Hg
HR, 64 beats/minute
Sodium, 140 mEq/L
Potassium, 4.3 mEq/L
Blood Urea Nitrogen (BUN), 13 mg/dL
Creatinine, 0.9 mg/dL

What classic signs and symptoms suggestive of psoriasis are demonstrated by M.M.?

Most psoriatic lesions are asymptomatic, but not always. Pruritus, for example, is noted in 50% of patients, and it can be severe.[18] Patients also report stinging or burning sensations.[19] The primary psoriatic lesion is a relapsing eruption of scaling papules that rapidly coalesce or enlarge to form circumscribed, erythematous, scaly plaques. The scale is adherent and silvery white and may reveal bleeding points when removed, called the Auspitz sign. Scales can become extremely dense on the scalp or macerated and dispersed in intertriginous areas.

The development of lesions of active psoriasis at the site of epidermal trauma is known as the Koebner phenomenon. Scratch marks, sunburn, or surgical wounds may heal, leaving psoriatic lesions in their place. The elbows, knees, scalp, gluteal cleft, fingernails, and toenails are favored areas of involvement. Extensor surfaces are affected more than the flexor surfaces, but the disease usually spares the palms, soles, and face. Nail beds may show punctate pitting, profuse collections of keratotic material, yellow-brown discoloration ("oil spot"), or onycholysis (nail plate separation) in approximately 50% of patients.[20] Psoriatic arthritis is a seronegative inflammatory arthritis that occurs in approximately 25% of all patients with psoriasis, with combined features of both rheumatoid arthritis and the seronegative spondyloarthropathies.[2,18]

Most patients (90%) have chronic localized disease (plaque type or psoriasis vulgaris), but several other presentations exist.[3] The most severe form of the disease is erythrodermic psoriasis, a condition of acute inflammatory erythema and scales involving greater than 90% of the BSA. Pustular psoriasis is generally localized to palms and soles, but there is also a generalized version. Both generalized pustular psoriasis and erythrodermic psoriasis can be accompanied by systemic symptoms (i.e., hyperthermia, tachycardia, edema, dehydration, shortness of breath) and can have life-threatening consequences (i.e., hypovolemia, electrolyte imbalance, septicemia) if not promptly treated.[21] Lesions of Guttate psoriasis are small, fine, erythematous scales, usually found on the trunk, arms, or legs, classically after β-hemolytic streptococcal pharyngitis. Flexural or inverse psoriasis is shiny and red, and typically lacks scales and looks more like intertrigo.[2] Of interest, psoriatic skin is rarely secondarily infected, because of the overexpression of the endogenous peptides cathelicidins and β-defensins.[20]

Systemic disorders that can have a causative association with psoriasis include type 2 diabetes mellitus, Chron's disease, metabolic syndrome, depression, and cardiovascular disease.[2,15–17] This increased risk is thought to be caused by the presence of endothelial activation, proinflammatory cytokines, and hyperlipidemia.[2,17,21] Disease severity is also thought to be a factor, because psoriatic patients with more severe conditions have an increased risk of metabolic, coronary heart disease or stroke compared with those with milder forms of psoriasis.[15]

M.M. presents with many classic signs of psoriasis, including symmetric, distinctive, chronic, and erythematous plaques covered with silvery scales on the extensor surfaces of the elbows and knees as well as the flexural surface of his arms and legs. He also shows scalp involvement, but does not appear to have plaques on his trunk or nail or systemic involvement. He exhibits the Auspitz sign and evidence of the Koebner phenomenon because

---

his lesions worsened after skin trauma from the sunburn. His report of pruritus is consistent with the presentation in 50% of patients.

CASE 41-1, QUESTION 2: What are the factors that can precipitate or aggravate psoriasis? What are the potential causes of M.M.'s psoriatic exacerbation?

A thorough medical history may reveal a cause of exacerbations of psoriatic lesions. Most patients report that hot weather, sunlight, and humidity help clear psoriasis, whereas cold weather has an adverse effect on its course. Anxiety or psychological stress is believed to contribute adversely. Viral or bacterial infections, especially streptococcal pharyngitis, may precipitate the onset or flare-up of psoriasis. Cuts, burns, abrasions, injections, and other trauma can also elicit the development of lesions. Any drug that causes a skin eruption to develop can exacerbate psoriasis via this response.

Drug-Induced Psoriasis

A number of drugs have been reported to exacerbate preexisting psoriasis, induce psoriatic lesions on apparently normal skin in patients with psoriasis, or precipitate psoriasis in persons with or without a family history of psoriasis (Table 41-1).[23] Antimalarial agents, such as chloroquine (taken by M.M.), may have an adverse effect on the course of psoriasis and can cause exfoliative erythroderma.[24] Hydroxychloroquine, however, has not shared this association (except for one case report) and usually induces a beneficial response in 75% of patients with psoriatic arthritis.[24] It is preferred over chloroquine in patients with psoriasis who need prophylactic treatment for malaria when both are effective against the particular plasmodium species in the area (see Chapter 81, Parasitic Infections).[24]

Lithium also can precipitate psoriasis and contribute to resistance to treatment through its effects on cell kinetics (increase in circulating neutrophils, accelerated neutrophil turnover, increased epidermal cell proliferation).[22] Psoriasis is not a general contraindication, however, to lithium therapy. More intensive psoriasis treatment can be used if these reactions occur, and lithium must be continued.[22]

β-Blockers and some nonsteroidal anti-inflammatory drugs (NSAIDs) also can precipitate a psoriasiform state.[22] Because both lithium and propranolol inhibit cyclic adenosine monophosphate (cAMP), cyclic nucleosides may play a role in the onset and clinical course of psoriasis. Chemotactic substances, including 12-hydroxyeicosatetraenoic acid and leukotrienes, may accumulate in the epidermis of some patients taking indomethacin, thereby precipitating psoriasis.[22]

When compared with other NSAIDs, indomethacin may selectively inhibit cyclooxygenase more than lipoxygenase pathways of arachidonic acid metabolism. As a result, indomethacin may have a more significant adverse psoriatic effect than other NSAIDs that have been reported to ameliorate psoriasis.[22]

Flare-ups of pustular psoriasis also can be precipitated by withdrawal from systemic corticosteroids or withdrawal from high-potency topical corticosteroids that are applied under occlusion to large areas.[25] Because of this problem and because fatalities have been associated with systemic corticosteroid use and withdrawal, systemic corticosteroids are not routinely used to treat psoriasis.

Chloroquine prophylaxis, a Caribbean sunburn, and triamcinolone tachyphylaxis probably all contributed to the exacerbation of M.M.'s psoriasis.

Categorization of Psoriasis

CASE 41-1, QUESTION 3: How would you categorize M.M.'s psoriasis?

The Self-Administered Psoriasis Area and Severity Index (SAPASI) is a validated, structured instrument that can be used for patient assessment of psoriasis severity and the response to therapy. It closely correlates with the standard clinician assessment instrument, Psoriasis Area and Severity Index (PASI), which includes quantification of the percentage of body involvement and severity of lesions.[26,27] A PASI of 75 (a ≥75% decrease in PASI score) at 3 months from baseline has become the most prominent marker to assess systemic agent efficacy (see http://escholarship.org/uc/item/18w9j736, which is Dermatol Online J. 2004;10(2):7, for a good reference to teach someone the PASI and SAPASI).[28]

Table 41-1

Drugs Reported to Induce Psoriasis

Anesthetics	Procaine
Antimicrobial agents	Amoxicillin, ampicillin, imiquimod, penicillins, sulfonamides, terbinafine, tetracyclines, vancomycin, voriconazole
Anti-inflammatory drugs	Corticosteroids (after withdrawal), NSAIDs (indomethacin, salicylates), mesalamine
Antimalarial agents	Chloroquine, hydroxychloroquine
Cardiovascular drugs	Acetazolamide, amiodarone, angiotensin-converting enzyme inhibitors (enalapril, lisinopril), β-blockers (atenolol, metoprolol, propranolol, timolol), calcium channel blockers (dihydropyridines, diltiazem, verapamil), clonidine, digoxin, gemfibrozil, quinidine
H_2-antagonists	Cimetidine, ranitidine
Hormones	Oxandrolone, progesterone

Opioid analgesics	Morphine
Psychotropics and neurologic agents	Lithium carbonate, venlafaxine, fluoxetine, carbamazepine, olanzapine, gabapentin, oxcarbazepine, tigabine, valproic acid, zaleplon
Miscellaneous	Potassium iodide, mercury, α-interferon, β-interferons, granulocyte-macrophage colony-stimulating factor (GM-CSF)

NSAIDs, nonsteroidal anti-inflammatory drugs.

Source: Kim GK, Del Rosso JQ. Drug-provoked psoriasis: is it drug induced or drug aggravated? J Clin Aesthet Dermatol. 2010;3:32–38; Basavaraj KH et al. The role of drugs in the induction and/or exacerbation of psoriasis. Int J Dermatol. 2010;49:1351; Facts & Comparisons eAnswers. Accessed August 21, 2015, with permission.

The National Psoriasis Foundation has released a clinical consensus statement on the classification of severity of disease. Rather than using a mild (less than 5% BSA affected) to moderate (5%–10%) to severe (greater than 10% BSA affected) classification system, the statement recommends two categories for patients: those who are candidates for topical therapy (less than 5% of BSA affected) and those who are candidates for systemic or phototherapy (more than 5% of BSA affected).[27,28]

M.M. would be categorized as having mild psoriasis and is a candidate for topical therapy because less than 5% of his BSA is currently affected by psoriasis.

TREATMENT OF MILD PSORIASIS

Many topical and systemic therapeutic agents are available, varying from simple topical emollients to systemic, highly potent immunosuppressant drugs for more recalcitrant conditions. Often, treatment modalities are chosen on the basis of disease severity, cost, convenience, and patient response. Patients with mild disease can generally be treated with topical therapy (Table 41-2). Patients with psoriasis covering more than 5% of the body require more specialized systemic or phototherapy treatment programs (Table 41-3). Nonpharmacologic treatment is also very important and can range from spa therapy to support groups.

Initial Therapy

NONPHARMACOLOGIC MODALITIES

CASE 41-1, QUESTION 4: What role can emotional support play in the comprehensive management of M.M.'s psoriasis?

Psoriasis is often more emotionally or psychologically disturbing than is recognized, and it may cause a reluctance from patients to participate in sports and other outdoor activities that may expose their skin to sunlight. Although exposure to sunlight helps most patients with psoriasis, there is an unwillingness to sunbathe if the lesions can be seen. Furthermore, if the psoriatic lesions become pruritic and are scratched, there can be further deterioration at the site. Many patients alter their lifestyles or use nontraditional medications and modalities, often in desperation.

Emotional support should begin with explanation of the psoriatic condition. M.M. needs to be reassured that many other people have the same condition, that the disorder is not contagious or fatal, and that it can be controlled, although no cure exists.[29] Patients usually are comforted in the knowledge that a wide range of treatments are available. Psychological encouragement and support are justified and make it easier for the patient to conscientiously apply messy topical treatments or to take toxic medications.

Table 41-2

Topical Agents for the Treatment of Psoriasis (Mild to Moderate; <5% Body Surface Area Involvement)

Treatment Modality	Advantages	Disadvantages
Emollients	Basic adjunct for all treatments; safe, inexpensive, reduces scaling, itching, and related discomfort	Provide minimal relief alone
Keratolytics (salicylic acid, urea, α-hydroxy acids [i.e., glycolic and lactic acids])	Reduce hyperkeratosis; enable other topical modalities to better penetrate; inexpensive	Provide minimal relief individually; nonspecific; salicylism (tinnitus, nausea, vomiting) with salicylic acid if applied extensively
Topical corticosteroids	Rapid response; control inflammation and itching; best for intertriginous areas and face; convenient, not messy; mainstay topical treatment modality for psoriasis	Temporary relief; less effective with continued use (tachyphylaxis occurs); withdrawal can produce flare-ups; atrophy, telangiectasia, and striae with continued use after skin returns to normalized state; expensive; adrenal suppression possible
Coal tar	Particularly effective for “flaky” scalp lesions; newer preparations are more cosmetically appealing; efficacy enhanced in combination with UVB (i.e., Goeckerman regimen)	Effective only for mild psoriasis or scalp psoriasis; inconvenient with difficult application; stains clothing and bedding, not skin; strong smelling; folliculitis and contact allergy (bronchospasm in atopic patient with asthma after inhalation of vapor); carcinogenicity in animals
Anthralin	Effective for widespread, refractory plaques; produces long remissions; short, concentrated programs preferred; enhanced efficacy in combination with UVB (i.e., Ingram	Purple-brown staining (skin, clothing, and bath fixtures); irritating to normal skin and flexures; careful application is required; can precipitate generalized psoriasis

	regimen)	
Calcipotriene and calcitriol	As effective as topical corticosteroids, although slower onset, without long-term corticosteroid adverse effects; convenient, well tolerated	Slow onset; expensive; potential effects on bone metabolism (hypercalcemia); irritant dermatitis on face and intertriginous areas; contraindicated during pregnancy
Tazarotene	Extended response; convenient (applied once daily, in gel formulation); maintenance therapy; effective on scalp and face; used in combination with topical corticosteroids	Slow onset; local irritation and pruritus; teratogenic (adequate contraception is required)
Ultraviolet B (UVB)	Effective as maintenance therapy; eliminates problems of topical corticosteroids	Expensive; office-based therapy; sunburn (exacerbates psoriasis); photoaging; skin cancers

Table 41-3

Agents for the Treatment of Severe Psoriasis (>5% Body Surface Area Involvement)

Treatment Modality	**Advantages**	**Disadvantages**
Psoralens plus UVA (PUVA)	80% efficacy; “suntan” effect is cosmetically desirable	Time-consuming; expensive, office-based therapy (restrictive); sunburn (exacerbates psoriasis); photoaging; both nonmelanoma skin cancer and melanoma; contraindicated during pregnancy and lactation
Acitretin	Not as effective as other systemic agents; efficacy enhanced if given with PUVA or UVB (i.e., RePUVA or ReUVB); less hepatotoxic than methotrexate	Teratogenic (contraception required); contraindicated with liver or renal dysfunction, drug or alcohol abuse, hypertriglyceridemia, hypervitaminosis A
Methotrexate	Effective for both skin lesions and arthritis, as well as psoriatic nail disease	Hepatotoxicity (liver biopsy may be indicated); bone marrow toxicity; folic acid protects against stomatitis (but not against hepatic or pulmonary toxicity); drug interactions; contraindicated during pregnancy and lactation, drug or alcohol abuse; use with caution during acute infections
Cyclosporine	Toxicities and short-lived remissions; used in patients with extensive disease who are unresponsive to other agents; however, given changing pathophysiology and increasing experience at lower dosages, increasing role in rotational therapy to	Renal impairment; suppressive therapy (relapse occurs when discontinued); increased risk of skin cancer, lymphomas, and solid tumors; phototoxic; contraindicated during pregnancy and lactation, and with hypertension, hyperuricemia,

	induce remissions	hyperkalemia, acute infections
Immunomodulators (etanercept, infliximab, adalimumab, golimumab, secukinumab, ixekizumab)	Specific, targeted therapy; effective for both moderate-to-severe skin lesions and arthritis; maintains remission	Expensive; parenteral therapy (often administered in an office-based practice); long-term safety unknown; increased risk of serious infections

PUVA, psoralens plus ultraviolet A light; RePUVA, retinoid-PUVA; UVA, ultraviolet A; UVB, ultraviolet B.

TOPICAL CORTICOSTEROIDS

CASE 41-1, QUESTION 5: What topical corticosteroid therapy is appropriate for M.M.?

Topical corticosteroids, the most widely prescribed treatment for psoriasis, are effective in the treatment of psoriasis because of their anti-inflammatory, antimitotic, immunosuppressant, and antipruritic properties.[25,30,31] These properties are explained by a reduction in phospholipase A_2, DNA synthesis, and epidermal mitotic activity, as well as their vasoconstrictive actions. They provide prompt relief, and patients find them convenient and acceptable. Mild-strength topical products or intermediate-strength products, for limited periods, can be used on facial lesions or intertriginous areas, or for maintenance therapy.[32] However, topical corticosteroids can, in a process called tachyphylaxis, also become less effective with continued use, and long-term use after the skin has returned to a normalized state leads to typical corticosteroid adverse effects (atrophy, telangiectasia, and striae). Thin-skinned areas (i.e., facial and intertriginous) are particularly susceptible.[33]

Psoriasis is generally a relatively corticosteroid-resistant disease; therefore, the more potent corticosteroids are frequently necessary, often with occlusion (e.g., plastic food wrap on top of the topical corticosteroid-treated area) (see Table 39-8 in Chapter 39, Dermatotherapy and Drug-Induced Skin Disorders, for a listing of topical corticosteroids by potency). Less-potent agents are more appropriate in intertriginous areas, on the face, and for maintenance. Potent fluorinated corticosteroid preparations should be used cautiously and only for short periods on the face and flexures, if at all. Potent topical corticosteroids may clear psoriasis in 25% of patients in 3 to 4 weeks, with 75% clearing in 50% of treated patients.[34]

Intermittent dosing or “pulse therapy” with several weeks between successive courses appears to yield the best long-term results and minimizes tachyphylaxis and adverse effects. An additional drawback of chronic corticosteroid therapy is an associated acute flare-up of psoriasis when corticosteroid therapy is terminated.[35] Continuous application for more than 3 to 4 weeks should be discouraged in patients with psoriasis, and systemic corticosteroids have no place in therapy.[33,34] Topical corticosteroids occasionally can cause a reversible suppression of the hypothalamic–pituitary–adrenal (HPA) axis, as indicated by a decrease in the morning plasma cortisol level.[33] For anything more extensive than mild disease and short duration of therapy, topical corticosteroids are best used in an adjunctive role. During a flare-up, corticosteroids help reduce inflammation, redness, and irritation and prepare the involved area for initiation of other potentially irritating, but more appropriate, maintenance topical treatments (e.g., coal tar, anthralin, calcipotriene, or tazarotene).

A short course of a potent topical corticosteroid is appropriate for this flare-up of erythematous plaque psoriasis in M.M. This will help reduce inflammation, redness, and irritation before possible initiation of more appropriate chronic topical treatments, such as calcipotriene, coal tar, or anthralin with ultraviolet B (UVB). Topical corticosteroids also may continue to be useful for M.M. on the face and flexures, where the alternative topical agents are poorly tolerated. His scalp psoriasis can be treated with corticosteroid preparations in gels, lotions, or aerosol sprays. This will allow for a more effective treatment of scaling and pruritus using an agent such as coal tar shampoo lathered into the scalp for 5 to 10 minutes, then rinsed out.

The response to once- or twice-daily corticosteroid application is as effective as or better than that observed with more frequent regimens (owing to a corticosteroid reservoir effect) and is much less expensive. M.M. should apply a topical corticosteroid preparation after a bath, at bedtime with occlusion, and possibly again during the day without occlusion. As the lesions subside, occlusion should be decreased or omitted, emollient use should increase, and the corticosteroid potency should decrease. After lesions have flattened, the topical corticosteroid products can be continued intermittently (e.g., 1–2 weeks on, 1–2 weeks off; or on alternate days [e.g., days 1, 3, 5, and 7]).

ALTERNATIVE TOPICAL TREATMENTS

CASE 41-1, QUESTION 6: M.M.'s acute psoriasis flare-up has responded well to a short course of topical corticosteroid. What alternative topical therapeutic regimens are available for patients such as M.M. who have localized or mild disease?

Effective alternative topical therapies available for patients with localized, mild psoriasis include crude coal tar, anthralin, calcipotriene, calcitriol, and tazarotene.[31] Although anthralin has irritating properties and both coal tar and anthralin generally stain clothing and skin and are somewhat inconvenient to apply, their efficacy is well established and may be an option to consider for initial management. Tachyphylaxis does not occur with chronic use of any of these alternative agents. Once the inflammation and erythema have lessened with corticosteroid use or when a twice-daily, high-potency corticosteroid regimen along with bedtime application of coal tar is ineffective, calcipotriene ointment applied twice daily or tazarotene gel applied once daily is effective in treating flare-ups and maintaining remission. Ointment vehicles are favored because they help moisturize the plaques (in contrast to creams, which dry the plaques further). Also, moisturizers or emollients are often helpful for psoriasis.[31]

Coal Tar

Crude coal tar is a complex mixture of thousands of hydrocarbon compounds.[31,36] It is a time-honored modality for treating psoriasis. It affects psoriasis by enzyme inhibition and antimitotic action (antiproliferative and anti-inflammatory).[36] The efficacy of the combination of tar and UVB light (i.e., Goeckerman regimen) led to its increased popularity beginning in the 1920s. Tar preparations of 2% to 10% are processed as creams, ointments, lotions, gels, oils, shampoos, and coal tar solution. Newer purified preparations, using refined coal tar, are less messy and more cosmetically acceptable, but perhaps not as effective.[36] Tar may be helpful for patients with mild-to-moderate disease, and tar shampoos are useful for psoriasis of the scalp. The potential severity of adverse drug effects from topical tar products is less than that from anthralin and much less than that from topical corticosteroids. Because tar, in every form, is messy, stains the skin, has an odor, and is low potency compared with anthralin, it has been relegated to second-line therapy for most patients, despite its moderate price and newer, more cosmetically appealing formulations.[33,37]

Tar preparations generally are used once or twice daily, and a bedtime application (as a shampoo or cream overnight) is particularly useful in psoriasis of the scalp. Patients should be warned about the staining properties of tar on clothing and bedding. Other adverse effects include photosensitivity, acneiform eruptions, folliculitis, and irritation dermatitis. Care should be taken to avoid use of tar on the face, flexures, and genitalia and with inflammatory psoriasis because of tar's irritant properties.

The polyaromatic hydrocarbons contained in coal tar may be metabolized to active carcinogens by epidermal microsomal enzymes. The incidence of hyperkeratotic lesions, including squamous cell carcinoma, is increased after prolonged industrial exposure to tar; however, extensive reviews of patients who have used tar preparations in psoriasis have not revealed an increased risk of carcinoma.[38]

Anthralin

Anthralin (dithranol in the United Kingdom) is a hydroxyanthrone derivative that inhibits DNA synthesis, mitotic activity, and a variety of enzymes crucial to reducing cell proliferation.[31,34] It is effective for treatment of widespread, discrete psoriatic plaques, but its use has declined in recent years with the availability of more cosmetically appealing preparations. Traditionally, it was applied as a stiff paste overnight and used in conjunction with coal tar baths and UVB light (i.e., Ingram regimen). Most cases of chronic plaque psoriasis clear in 3 weeks. The primary disadvantages of anthralin are its irritant nature and property of staining skin and clothing. Anthralin also can precipitate generalized psoriasis if applied to unstable psoriasis (i.e., plaque transformation to pustular form).

When used, the most current anthralin regimen is a once-daily application of a 1% or 1.2% cream (Dritho-Crème HP and Zithranol-RR, respectively) for a short-contact anthralin therapy (SCAT; apply for 20–30 minutes, then wash off). One factor that limits its use is the brown-to-purple staining of the skin, hair, clothing, furniture, and bedding that occurs immediately with use. Plastic gloves should be used, as well as old bed linens and clothing for sleep. If possible, contact with the face, eyes, mucous membranes, and nonpsoriatic skin should be avoided because of irritant properties. Irritation is a problem and should be evaluated every 48 hours. Patients can apply petroleum jelly around lesions to avoid anthralin contact with unaffected skin. Anthralin is used daily for clearing of psoriasis, then once or twice weekly for maintenance therapy, after a response is seen at 2 to 3 weeks. Short-course regimens clear 32% of lesions and produce greater than 75% improvement in half of patients after 5 weeks. These regimens are comparable in effectiveness to the Ingram regimen and topical corticosteroids, and are associated with fewer adverse drug events.[33,39]

Calcipotriene

Calcipotriene (calcipotriol in Europe) is a topical vitamin D_3 analog that suppresses keratinocyte proliferation and has anti-inflammatory effects.[31,40] It can be applied twice daily as a cream, ointment, foam, or solution. Although systemic absorption is slight and the vitamin D effects of calcipotriene on calcium and bone metabolism are about 100 to 200 times less than those of 1,25-dihydroxyvitamin D_3, serum calcium levels and urinary calcium excretion should be monitored to prevent serious adverse effects. A 100-g/week limit should be enforced; exceeding this limit results in negative effects on calcium and bone metabolism. Other adverse effects of calcipotriene, such as lesional and perilesional irritation, burning, stinging, pruritus, erythema, and scaling, occur in about 30% of patients and preclude use on the face or in intertriginous areas. When used concurrently with topical salicylic acid, calcipotriene will be chemically inactivated.[41]

Calcipotriene may be the topical maintenance treatment of choice in patients with generalized mild-to-moderate psoriasis. The drug is usually effective, relatively easy to apply, odorless, and nonstaining (cream, ointment, or scalp solution). Most patients see improvement, although not clearing, of psoriatic plaques at 2 weeks when treated with calcipotriene, often in combination with potent topical corticosteroids.[42] A maximal response is usually seen at 6 to 8 weeks. Of treated patients, 57% experience greater than 75% clearance of psoriatic plaques, which is comparable to that achieved with corticosteroids, albeit slower in onset and associated with more skin irritation.[30,39] Tachyphylaxis has not been a problem.[42]

Calcitriol

Calcitriol is an active form of vitamin D_3 that blocks keratinocyte proliferation. The ointment should be applied twice a day, while avoiding the face, eyes, and lips. Use should not exceed 200 g/week. Hypercalcemia has occurred in about 25% of patients, and calcitriol should be held until calcium levels return to normal. Nephrolithiasis, hypercalciuria, and irritation of the skin have been reported with calcitriol use. Skin irritation, however, is less than with the use of calcipotriene. Caution should be exercised when combining calcitriol with phototherapy because it is inactivated by ultraviolet light and its vehicle blocks ultraviolet light.[43] Therefore, patients should apply calcitriol after phototherapy. Calcitriol effects are seen as early as 2 weeks, peak in about 8 weeks, and equal calcipotriene efficacy. Approximately 65% of patients continued to show improvement at 52 weeks of therapy.[44]

Tazarotene

Tazarotene is a topical synthetic retinoid that is rapidly converted to its biologically active metabolite, tazarotenic acid.[31,45] By interacting with the predominant retinoid receptors on the skin surface regulating gene transcription, retinoic acids normalize abnormal keratinocyte differentiation, reduce hyperproliferation, and decrease inflammation associated with psoriasis.[45] Treatment success rates compare favorably with corticosteroids (52% clearing of all lesions; 70% clearing of trunk and limb lesions). The antipsoriatic effects of tazarotene are sustained for a longer period after treatment compared with corticosteroids.[34,46] Because local skin irritation and pruritus are common adverse effects of tazarotene use, combination therapy with corticosteroids not only provides additive antipsoriatic effects, but also reduces retinoid-induced irritation.[47] Because oral retinoids are known teratogens, tazarotene is a category X drug and is contraindicated during pregnancy. Women should be warned of the potential risk and the need to use adequate contraception while using these preparations.[45,46]

Similar to calcipotriene, tazarotene works slowly. It is available as a gel, which many patients find more cosmetically appealing than an ointment. It is also effective in a once-daily regimen, which might help to improve compliance.

PHOTOTHERAPY

Phototherapy with ultraviolet (UV) light has a long history of use in the treatment of psoriasis. Unlike immunosuppressive agents, phototherapy is thought to target effector immune cells and upregulate regulatory T cells. Phototherapy also reverses epidermal barrier abnormalities, thus restoring cutaneous homeostasis.[48] If available locally, UV light can be used as an outpatient modality, and newer options for home treatments have become commonplace.[49] This modality produces comparatively long-lasting remissions and is pleasant to use with relatively low toxicity at a reasonable cost when compared with biologic agents.[50] Different protocols require daily exposure or multiple times per week for varied lengths of time, depending on patient variables. The optimal effect of UVB on psoriasis is a dose that produces minimal erythema at 24 hours. The usual time to induce clearing of psoriasis is approximately 4 to 6 weeks.

Ultraviolet B

Ultraviolet B light, sunburn spectrum 290 to 320 nm, induces pyrimidine dimers, inhibits DNA synthesis, and depletes intraepidermal T cells found in psoriatic epidermis (i.e., UVB has antiproliferative and local immunologic effects).[25] UVB light, unlike ultraviolet A (UVA) light, is effective without additional sensitizers (i.e., psoralens). UVB therapy is generally considered pleasant to use and relatively nontoxic. Typically, 60% of patients with chronic plaque psoriasis experience clearing, and an additional 34% achieve a 75% clearance with UVB treatment for 7 to 8 weeks.[35] Humidity and heat from sunlight provide additional positive effects. Narrowband UVB (NB-UVB) phototherapy, having sunburn spectrum of 311 nm, has been found to be more effective than broadband UVB (BB-UVB)[51]; however, it has not demonstrated superiority to psoralens plus ultraviolet A (PUVA) light therapy in terms of clearing psoriatic lesions.[52] In a literature review comparing PUVA with NB-UVB, PUVA tends to clear psoriatic lesions more reliably, with fewer sessions, and with longer-lasting clearance; however, this must be balanced with the increased risk of PUVA in causing skin cancers. [53] In another literature review, NB-UVB was found to be more effective than BB-UVB and was also safer than PUVA.[54]

The greater efficacy of PUVA, however, may be offset by the short-term adverse effects of psoralens (e.g., nausea, headaches), the greater incidence of phototoxic reactions (erythema), and the inconvenience of wearing photoprotective eyewear after treatments. At present, NB-UVB may be preferred because the available data suggest no or minimal risk of carcinogenesis compared with PUVA, it is safer to use in children and pregnant patients, it is devoid of drug-related (psoralen) adverse drug events, and there is no requirement for the use of posttreatment photoprotective eyewear. Although not definitively proven, it is hypothesized that NB-UVB will produce less long-term photodamage and fewer skin cancers than PUVA.

Ultraviolet B treatments are administered 3 times weekly. The use of pretreatment emollients (e.g., petrolatum, mineral or “baby” oil, Eucerin) applied before UVB exposure, long thought to improve results by aiding in descaling or by enhancing UVB penetration, actually inhibits its penetration and should not be used.[55] After the skin clears, therapy is discontinued gradually over the course of 2 to 4 months to prolong remission. The risks of UVB radiation and sunlight are similar: sunburn, photoaging, and skin cancer.

Regimens combining UVB with anthralin (Ingram regimen) or tar (Goeckerman regimen) have been used for years, theoretically taking advantage of the photosensitizing properties of tar and anthralin. The Goeckerman regimen, which consists of use of UVB light and 1% to 10% crude coal tar, involves daily application of coal tar for at least 4 hours, along with UVB exposure. Crude coal tar has been shown to be superior to cleaner tar preparations and other tar derivatives, using a 2-hour application before broadband UVB exposure. A petrolatum base, with a greasy sensation, was not superior to hydrophilic ointment, which has better cosmetic appeal and is easier to apply.[56]

The Ingram regimen combines daily application of anthralin plus coal tar baths with exposure to UVB light, with combination results superior to UVB monotherapy. These two regimens are reported to clear plaques in 75% of patients treated for 6 weeks for chronic plaque psoriasis (vs. 56% with UVB alone). The total number of treatments and the total UVB dose required for clearing are less in the combination groups.[57] Methods of classical treatments are not standardized, and different protocols in different treatment settings are used. Combinations of anthralin with superpotent corticosteroids or with coal tar may be preferred if systemic therapies are not effective or contraindicated.[58] Both the Goeckerman and Ingram regimens can decrease the severity of widespread psoriasis in 3 to 4 weeks, induce remissions that last for weeks to months, and may reduce the long-term adverse effects of UVB exposure.[57] A newer interest is the use of the Goeckerman regimen in those patients who are refractory to biologic agents.[59]

In summary, the first step in the treatment of M.M. would be a high-potency corticosteroid ointment twice daily, along with a coal tar ointment at night. If this is ineffective, either calcipotriene ointment can be added twice daily or tazarotene gel can be used once a day for 8 weeks. Once control is achieved, M.M. may use calcipotriene or tazarotene without topical corticosteroids; these products do not cause corticosteroid atrophy and do not have the potential for systemic adverse effects associated with topical corticosteroids. Topical anthralin, with or without UVB, can be used for resistant cases.

TREATMENT OF SEVERE PSORIASIS

CASE 41-2

QUESTION 1: G.L., a 42-year-old man with a several-year history of psoriasis (fairly localized), presents with diffuse, erythematous plaque-like lesions now extending over 80% of his body. The areas have become inflamed, and application of his maintenance topical medication (anthralin) causes pain and irritation. He expresses frustration with the messiness of the current topical regimen. He has reinstituted topical corticosteroids, which helped the redness and itching but are too expensive to use long term. He is free of cardiovascular, renal, or hepatic disease and takes no systemic medications. He is self-employed as a business consultant. Which “systemic” therapy would be most appropriate for G.L.’s psoriasis at this point?

Systemic therapies for psoriasis include PUVA, acitretin (the systemic retinoid), methotrexate; cyclosporine; and apremilast. Biologic agents, including the tumor necrosis factor (TNF)-α inhibitors (infliximab, etanercept, adalimumab, golimumab, ustekinumab, and secukinumab), have also been used for psoriatic lesions.[60]

Although PUVA and methotrexate are commonly used, cyclosporine and the immunomodulatory agents are being used increasingly more as experience is gained with them for treatment of severe psoriasis.[25,61] The choice of agents depends on patient and drug characteristics. Because patients with psoriasis generally have the disease for the rest of their lives, the goal of treatment is not just safe and effective resolution of lesions at a specific point in time, but also maintenance therapy. Long-term maintenance therapy for psoriasis can generally be achieved even with a weaning or discontinuation of UVB, PUVA, and methotrexate. From a histologic perspective, these drugs have been shown to induce remittive cellular changes. In contrast, partial-to-full doses of acitretin or cyclosporine are necessary to maintain therapeutic effects, because they induce suppressive rather than remittive histopathologic changes. For example, relapse will occur in most patients in a predictable manner 2 to 4 months after cyclosporine is discontinued.[62] Similarly, biologic therapy has demonstrated a very satisfactory antipsoriatic effect; however, the loss of the therapeutic response over time has been reported. Of interest, the addition of NB-UVB to the use of immunomodulatory agents that have lost this response in the control of moderate-to-severe cases in adults has been demonstrated to recover the initial response.[63]

Photochemotherapy

Photochemotherapy combines psoralens with UVA light in the 320- to 400-nm spectrum. The psoralens (methoxsalen, 8-methoxypsoralen, and trioxsalen) are a group of photoactive compounds that, on absorption of UV light, are both antiproliferative and immunomodulatory. When photoactivated by UVA, psoralens form monofunctional adducts and cross-links with pyrimidine bases. PUVA also inhibits cytokine release and depletes both epidermal and dermal T cells. As measured by extent of T-cell depletion and decreases in delayed hypersensitivity, PUVA has greater immunomodulatory effects in the skin than UVB. Use of PUVA for scalp or nail involvement is limited, however, because of lower exposure.[64] Remissions are longer in duration than with UVB. Psoralens are not active without UVA.

Photochemotherapy is used to control severe, recalcitrant, disabling plaque psoriasis. After 10 to 20 treatments over the course of 4 to 8 weeks, more than 80% of patients experience clearing of symptoms, which can be maintained with periodic (twice monthly) treatments.[64] UVA penetrates the skin more deeply than UVB and may have marked effects on the dermis. The use of PUVA requires careful consideration and adherence to strict photoprotective measures. Patients unwilling to adhere to PUVA-related precautions may prefer UVB treatment because it is much less restrictive.

The peak range for UVA light's therapeutic action is between 320 and 335 nm. The most widely used agent, 8-methoxypsoralen, at an oral dosage of 0.6 to 0.8 mg/kg of body weight rounded to the nearest 10 mg, is taken approximately 1.5 hours before exposure to UVA light. [52] The initial dose is selected on the basis of the patient's skin type (i.e., ease of sunburn and inherent skin color). Other options for combination therapy with UVA include calcipotriol-PUVA (D-PUVA) and retinoid-PUVA (RePUVA). Both of these modalities have been shown to have greater efficacy as compared with PUVA alone.[51]

Acute adverse phototoxic effects, such as partial-thickness burns, erythema, and blistering, are dose-related and, therefore, are a serious yet preventable complication of PUVA photochemotherapy. [65] Other acute adverse drug effects include nausea, lethargy, headaches, pruritus, and hyperpigmentation. Topical corticosteroid therapy should be continued until the psoriasis is brought under control. If topical corticosteroids are discontinued at the start of PUVA, an exacerbation of psoriasis usually occurs. Patients should wear protective clothing (with long sleeves and high necklines), use sunscreens that filter out both UVA and UVB, and wear sunglasses that block UVA after PUVA (see Chapter 42, Photosensitivity, Photoaging, and Burns). Because methoxsalen has a short half-life and 80% is eliminated within 6 to 8 hours, physical barriers are most important during the 8 hours immediately after PUVA therapy.

Of greater concern are the potential long-term adverse effects: mutagenicity, carcinogenicity, and cataract formation. A review of studies demonstrated an increased risk of nonmelanoma skin cancers following PUVA. [66] Squamous cell carcinoma has been associated with cumulative PUVA treatments (11-fold increase in patients who receive more than 260 treatments compared with patients who received fewer than 160 treatments).[67] Male patients have an increased risk of having genital squamous cell carcinoma. A relationship exists between the exposure to PUVA and the risk of malignant melanoma. At present, there appears to be a dose-dependent increase in the risk of melanoma associated with high-dose exposure to PUVA. The risk is first manifested at least 15 years after initial exposure to PUVA.[67–69] A cohort study evaluated over 13,000 patients for cancer risk by treatment modality. Patients treated with coal tar did not have increased risk of malignancies, both dermatologic and nondermatologic, and it is considered a safe option for treatment.[70] Long-term maintenance and high cumulative dosages should be avoided. Shielding the face and genitalia during treatment and performing annual examinations to detect skin cancer at an early stage may lessen the risk of long-term adverse effects of photochemotherapy.

Topical psoralens are extremely photosensitizing and hence difficult to administer. Application of methoxsalen 0.1% followed by small UVA doses (i.e., ≤20% of the level of usual doses for oral PUVA) has been used, however, to treat localized areas and to prevent adverse gastrointestinal effects.[64]

SYSTEMIC PHARMACOTHERAPY

Acitretin

Second-generation systemic retinoids are effective for treatment of recalcitrant psoriatic disease. Antipsoriatic effects stem from the drug's ability to modulate epidermal differentiation and immunologic function in addition to an anti-inflammatory action.[71] This latter effect may alleviate the arthritis that accompanies psoriasis.[25,64] Acitretin, a systemic second-line therapy for severe psoriasis, is the principal metabolite of etretinate. It is 50 times less lipophilic than etretinate and has a considerably shorter elimination half-life; however, patients taking any retinoid product should still be monitored closely. It is indicated for patients who have received extensive radiation with PUVA, as a pretreatment for PUVA (1–3 weeks) to accelerate the response rate, for patients who fail to respond to UVB with anthralin or tar, or for patients who are not candidates for methotrexate.[72] Most patients require maintenance or intermittent therapy to prevent relapses.[73] Response to acitretin should be assessed at 4-week intervals with dose titrations to reach therapeutic effect with minimal adverse events.[74]

Numerous other adverse effects are associated with acitretin use, including hypervitaminosis A syndrome (i.e., dry skin, skin thinning and fragility, chapped lips, dry nasal mucosa, skin peeling, alopecia, and nail dystrophy), retinoid rash, extraspinal tendon and ligament calcification and bone changes in children, hyperlipidemia with elevated levels of serum triglycerides and cholesterol, and liver enzyme alteration and hepatitis.[75] Many patients find the adverse effects of the retinoids intolerable and discontinue treatment. Topical corticosteroids can reduce some of the cutaneous retinoid adverse effects.

Acitretin is teratogenic and accumulates in fatty tissues, where it is slowly released into the bloodstream for up to 1 year after final administration.[71] Therefore, strict contraception during treatment and for 2 to 3 years afterward is recommended in women of childbearing age.[69,76] Patients also need to be advised not to donate blood while taking acitretin and up to 1 year after the end of treatment.[71]

Immunosuppressive Agents

METHOTREXATE

Methotrexate, a folic acid analog, inhibits dihydrofolate reductase needed for synthesis of several amino acids, pyrimidines, purines, and, subsequently, DNA, RNA, and protein synthesis. Methotrexate therapy greatly suppresses rapidly proliferating cells, such as those in psoriatic skin. Antipsoriatic mechanisms of methotrexate action include inhibition of keratinocyte differentiation and immunomodulation by destruction of lymphoid cells.[25,77]

Unlike other cytotoxic drugs, methotrexate produces antipsoriatic effects at dosages that are much lower than those used in cancer chemotherapy. Methotrexate is relatively safe and well tolerated, yet the long-term concerns for myelosuppression and hepatotoxicity (fibrosis and cirrhosis) and the need for periodic liver biopsies can discourage many patients and physicians from using it.[78,79] Alcohol and methotrexate are a particularly potent hepatotoxic combination. Patients with psoriasis receiving methotrexate have a 2.5- to 5-fold higher incidence of advanced liver changes than patients with rheumatoid arthritis receiving comparable regimens.[80] Methotrexate hepatotoxicity may be related to both cumulative doses and constant blood levels. Daily administration has been replaced by weekly dosage schedules for this reason. Liver chemistry tests (i.e., serum alanine aminotransferase, serum aspartate aminotransferase, serum albumin, and bilirubin) can be within normal limits, even in the presence of methotrexate-induced liver disease.[77] Therefore, consensus guidelines call for risk stratification for liver biopsies in all patients with psoriasis at baseline, and at intervals of approximately 1 to 1.5 g of cumulative methotrexate dose. Liver function tests, bilirubin, and albumin should be monitored monthly for the first 6 months, and then every 1 to 2 months thereafter.[77]

Bone marrow depression, nausea, diarrhea, and stomatitis are other adverse effects associated with methotrexate. Pneumonitis can occur early in the course of treatment, particularly when methotrexate is given at higher dosages similar to those used in cancer chemotherapy regimens. Folic acid, 1 mg daily, may prevent some of these adverse events, but not hepatitis or pulmonary toxicities. Teratogenesis and miscarriages have occurred, and methotrexate may cause reversible oligospermia. A number of clinically significant drug interactions may enhance the toxicity of methotrexate. Drug interactions are most likely to be clinically relevant problems in patients with decreased renal function.[77]

Relative contraindications to treatment with methotrexate include decreased renal function, significant abnormalities in liver function (i.e., fibrosis, cirrhosis, hepatitis), pregnancy or breastfeeding, anemia, leukopenia, thrombocytopenia, active peptic ulcer disease or infectious disease (tuberculosis, pyelonephritis), alcohol abuse, and patient unreliability.[77] Conception must be avoided during methotrexate therapy and for at least 3 months after cessation of methotrexate in men or one full ovulatory cycle in women.[77] Monthly monitoring of complete blood count with differential and a platelet count should be performed 7 to 14 days after starting therapy, and every 2 to 4 weeks for the first few months, then every 1 to 3 months.

Renal function tests (i.e., serum creatinine, BUN) should be obtained at 2- to 3-month intervals.

CYCLOSPORINE

The positive dermatologic effects of cyclosporine highlight the importance of immune alterations in the pathogenesis of psoriasis. The toxicity and the short duration of remissions induced by cyclosporine and tacrolimus limit their usefulness. Cyclosporine is generally reserved for patients with extensive psoriasis who have not responded adequately to topical agents, UVB, PUVA, and other systemic agents.

In psoriasis, cyclosporine primarily acts by inhibition of calcineurin, which is necessary for interleukin-2 (IL-2) production. Interleukin-2 amplifies helper T cells and cytotoxic lymphocytes. Decreased IL-2 production leads to a decline in activated CD4 and CD8 cells in the epidermis. Cyclosporine also inhibits TNF-α and interferon-α_2, both of which are involved in the chemotaxis of inflammatory cells; it inhibits release of cytokines and the growth of keratinocytes.[81]

Cyclosporine is used at relatively low dosages for the treatment of psoriasis. In general, 2.5 to 6 mg/kg of cyclosporine, in one or two divided doses, is recommended for the initiation of psoriasis treatment. Rapid improvement of plaque psoriasis is expected, with 30% of patients experiencing clearing of psoriatic plaques and 50% achieving greater than 75% clearing of lesions within 10 weeks at a dose of 2 to 3 mg/kg/day. Many people relapse 2 to 4 months after the discontinuation of cyclosporine therapy.[82] Cyclosporine showed comparable efficacy to methotrexate in patients with psoriasis with average doses of 4.5 mg/kg/day and 20.6 mg/week, respectively.[78]

Drug-induced renal impairment is common with cyclosporine use, but usually reversible. Hypertension, secondary to vasoconstrictive effects on the smooth muscle of renal blood vessels or drug-induced arteriolar hyalinosis, is dose dependent and gradual

---

in onset. Blood pressure and serum creatinine should be monitored closely in patients receiving cyclosporine.[79] Hypokalemia, hypomagnesemia, hyperuricemia, gingival hyperplasia, hypercholesterolemia, hypertriglyceridemia, adverse gastrointestinal effects, hypertrichosis, fatigue, myalgia, and arthralgia also have been attributed to cyclosporine therapy.[80] The risk of skin cancer, lymphomas, and solid tumors can also increase.[81,82] Patients should be cautioned about excessive sun exposure and should not receive concurrent UVB or PUVA treatment during cyclosporine therapy because of an increased risk of nonmelanoma skin cancers.[83]

PUVA is effective in 80% to 90% of patients, and G.L.'s severe, extensive, plaque psoriasis should be expected to respond accordingly. The systemic drugs (e.g., methotrexate, cyclosporine) may be preferred if G.L. had systemic symptoms (e.g., psoriatic arthritis). Although 3 times weekly PUVA treatments can be disruptive to work schedules, G.L. is self-employed and presumably has some flexibility in his working hours, and this would be a good option for him.

Phosphodiesterase 4 (PDE4) Inhibitors

Apremilast is an oral PDE4 inhibitor with efficacy in the treatment of moderate-to-severe plaque psoriasis and reduces immune responses by increasing intracellular cAMP in T cells. This results in decreased expression of cytokines and other proinflammatory mediators, but increased expression of anti-inflammatory mediators.[84] Mesenchymal cells, which express PDE4, are found in keratinocytes within the dermis, smooth muscle, and vascular endothelium.[85]Two phase IIb studies demonstrated that patients randomized to apremilast 20 mg twice daily achieved 24% and 29% PASI-75 at weeks 12 and 16, compared to 10.3% and 6% of those in placebo groups.[86,87] Of note, all patients enrolled had previously failed other therapy or were receiving concurrent therapy for psoriasis. Therefore, apremilast should not be considered a first-line agent in the treatment of plaque psoriasis.[86]

The recommended dose for apremilast is a 5-day titration up to 30 mg twice daily. The most common adverse effects with apremilast include gastrointestinal (i.e., diarrhea and nausea) and headache. Other adverse effects included upper respiratory infections and rebound psoriasis in 0.3% of patients after discontinuation of therapy. Apremilast is metabolized via the CYP 3A4 pathway and therefore should be evaluated for any drug–drug interactions prior to starting therapy. The dose of apremilast should be reduced when used in patients with impaired renal function (e.g., creatinine clearance less than 30 mL/minute).[85–87]

ROTATIONAL THERAPY

CASE 41-2, QUESTION 2: Does G.L. have options to decrease adverse effects and cost of his PUVA therapy?

No form of therapy used in psoriasis today is without toxicity. Rotational therapy involves the use of alternating monotherapies, which allows the patient to experience extended intervals of a particular treatment.[88] When used in long-term maintenance, rotational therapy limits adverse effects associated with either long-term use of one specific agent or the additive or synergistic interactions when multiple therapies are used concurrently. As discussed, the relative risk of skin cancer associated with PUVA increases after 160 treatments. If a patient in remission is rotated off PUVA to another treatment after 100 exposures, the skin has time to recuperate from the light therapy, and PUVA can eventually be reinstated presumably with lesser risk. Rotational therapy assumes that the patient can tolerate three to four alternative treatments with unrelated toxicity profiles.[88] By rotating each treatment after 12 to 18 months of cumulative use, the potential for long-term toxicity associated with any single treatment is minimized. With this theoretic rationale, cyclosporine could be used for a limit of possibly 3 to 6 months, thus inducing a remission. The patient could then be rotated to another treatment (e.g., methotrexate or PUVA) for maintenance.

Psoralens and UVA irradiation become noticeably effective in 80% to 90% of patients in 6 to 8 weeks.[25] The regimen is time consuming because UV radiation treatments must be administered at least 3 times a week. Methoxypsoralen (8-MOP) is administered (0.6–0.8 mg/kg of body weight), followed by UVA (dose selected based on skin type, ease of sunburn, and inherent skin color) about 75 to 90 minutes later when psoralen blood levels peak. PUVA-induced erythema generally appears later than with UVB therapy, reaching a peak by 48 hours. Consequently, treatment should not be administered more frequently than every second day. The time to produce clearing of psoriatic plaques with PUVA takes longer than with UVB therapy (average 10 weeks compared with ≤3 weeks for UVB).[64] PUVA treatment must be decreased slowly once plaques have been cleared (frequency of treatment is reduced during 2–3 months) to prevent recurrence of psoriatic plaques. In contrast, UVB therapy can be ceased abruptly.

Taking time off from work 3 times weekly for photochemotherapy can be disruptive to some patients' work or school schedules. Technologic advances in home phototherapy equipment have provided patients with choices for therapy in settings that are familiar and comfortable, in addition to continued improvements in efficacy and safety.[41] Advantages of home phototherapy include improved quality of life, greater convenience, lower cost, and less time lost from work and social activities.

Psoralens and UVA should be avoided in patients with a history of skin cancer, in children, during pregnancy, in patients who are immunosuppressed, and in those who have light-colored skin that burns rather than tans. Absolute contraindications to treatment with PUVA include a history of photosensitivity diseases (i.e., lupus erythematosus, porphyria), idiosyncratic or allergic reactions to psoralens, arsenic intake, and exposure to ionizing radiation, skin cancer (relative contraindication), pregnancy, and lactation. Techniques to minimize cumulative dosage of radiation and reduce the risk of long-term adverse effects of photochemotherapy include use of sunscreen, protective clothing, and sunglasses, and use of combination therapy (RePUVA). Other photosensitizing drugs (e.g., fluoroquinolones, phenothiazines, sulfonamides, sulfonylureas, tetracyclines, and thiazides) should be avoided in patients receiving PUVA.

Rotational therapy could be considered at a later time, depending on G.L.'s response and tolerance of PUVA.

PSORIATIC ARTHRITIS

CASE 41-3

QUESTION 1: R.T. is a 46-year-old male aerospace machinist with psoriasis and increasing joint complaints. He describes a flare-up during the last month involving predominantly the middle finger of his right hand. He also has arthralgias of the shoulders, knees, and the rest of his hands. Concomitantly, his skin disease has once again become active, despite nightly betamethasone dipropionate administration. He has a history of chronic depression and alcoholism, although he is currently sober and not being treated with antidepressant medications. Physical examination reveals a significant amount of tenderness of the right third metacarpophalangeal joint, without a great deal of active synovitis. He also has a moderate effusion of his right knee, but the rest of the

---

joint examination is otherwise benign. Active psoriatic lesions are noted on his feet, knees, and elbows, and he has characteristic psoriatic nail changes. An erythrocyte sedimentation rate is mildly elevated. Which systemic therapy would be most appropriate to treat both R.T.'s skin and joint complaints?

Psoriatic arthritis (PsA) is a distinct form of inflammatory arthritis that is usually seronegative for rheumatoid factor. In various reports, 6% to 39% of patients with psoriasis experience PsA, and the prevalence is increased among patients with severe cutaneous disease.[18] Nail involvement occurs in greater than 80% of patients with PsA, as compared with 30% of patients with only cutaneous psoriasis.[18,89] Five clinical subsets of PsA have been identified: distal interphalangeal arthritis (classic; 5%–10%, often accompanied by nail changes), arthritis mutilans (5%, starts in early age, accompanied by osteolysis with severe deformities of fingers and toes), symmetric polyarthritis (rheumatoid-like; <25% incidence, milder course), asymmetric oligoarthritis (most prevalent; 70%, proximal and distal interphalangeal joints, metacarpophalangeal joints, knee, and hip), and spondylitis (5%–40%, often asymptomatic).[90]

The presentation of R.T. is representative of asymmetric oligoarthritis. Traditionally, treatment of this form of PsA consists of an NSAID, local corticosteroid injections, and immunosuppressive agents, including TNF inhibitors. Despite scant clinical evidence of efficacy, NSAIDs are commonly used to suppress the musculoskeletal symptoms of PsA, but do not induce remissions.[89] Systemic corticosteroids are avoided because they destabilize psoriasis (transformation to pustular forms), induce resistance to other effective therapies, and re-exacerbate the skin disease during withdrawal.[91] PUVA and acitretin have negligible anti-arthritic efficacy.

Methotrexate

Methotrexate is one of the most common agents used to produce symptomatic benefits (approximately 30%) in patients with PsA, but data on its efficacy to inhibit articular damage are limited.[91,92] TNF-α inhibitors have also been demonstrated to slow down or halt radiographic progression.[93] For mild joint disease, NSAIDs and intra-articular glucocorticoid injections may be adequate, whereas moderate-to-severe joint disease optimally will be treated with systemic oral disease-modifying antirheumatic drugs or biologics.After a sufficient trial of an NSAID, initiation of a second-line agent such as methotrexate before progression to a biologic intervention is a reasonable approach to manage R.T.'s arthralgias in his shoulders, knees, and hands, as well as his active skin disease.

After obtaining the history and physical examination, baseline laboratory tests should be obtained, which include a complete blood count, platelets, renal function tests (serum creatinine, BUN), liver function tests (LFTs: alanine aminotransferase, aspartate aminotransferase, alkaline phosphatase, and bilirubin), HIV antibody determination, and a purified protein derivative (PPD). Although standard in the past for all patients about to receive methotrexate therapy, a baseline aspiration needle biopsy of the liver, not an innocuous procedure, is obtained currently only in those patients with preexisting severe liver disease.[77] Patients with one or more risk factors for hepatic fibrosis (e.g., persistent abnormal liver chemistries, previous exposure to hepatotoxic agents, obesity, hyperlipidemia, diabetes mellitus, and family history of inheritable liver disease) should receive a baseline liver biopsy and a biopsy every 2 to 6 months until the drug's efficacy and a lack of toxicity have been established. A repeat liver biopsy after 1.0 to 1.5 g of methotrexate has been received is appropriate because it is rare for life-threatening liver disease to develop at this lower cumulative dose.[94]

Therapy with methotrexate usually is initiated with a 2.5- to 5-mg test dose.[77] If no idiosyncratic reaction occurs, doses are gradually increased to a maintenance dose of 10 to 25 mg/week. Methotrexate is best given in a single weekly oral dose or in three 2.5- to 7.5-mg doses at 12-hour intervals during a 24-hour period (e.g., 8 AM, 8 PM, and again at 8 AM). With the introduction of biologic agents in the management of psoriasis and its associated conditions, an increased level of monitoring has developed. Hepatotoxicity, however, may not be apparent on routine laboratory evaluation. Every 4 to 12 weeks, LFTs should be obtained, preferably at least 1 week after the last methotrexate dose because these values are often elevated 1 to 2 days after therapy. If a significant abnormality in the LFTs is noted, therapy should be withheld for 1 to 2 weeks, and the LFT testing should be repeated. LFT values should return to normal in 1 to 2 weeks. If significantly abnormal LFTs persist for 2 to 3 months, a liver biopsy should be considered. As noted previously, a liver biopsy is recommended when the cumulative dosage level reaches 1.0 to 1.5 g, as well as after each subsequent 1.5-g increase in the cumulative dose. Liver function abnormalities may improve after cessation of methotrexate therapy for 6 months.

Immunomodulatory Therapy

CASE 41-3, QUESTION 2: During a follow-up visit to his family physician several months later, R.T. had several somatic complaints that led to a diagnosis of recurrent depression. Subsequent history reveals that he also has resumed use of alcohol. He tends to drink four to five beers a night on weekends or when he is feeling low, although he does admit that his level of alcohol use is sometimes higher. His skin lesions are relatively well controlled, but joint complaints have persisted. What additional options now exist for R.T.?

Methotrexate should be discontinued because the risks probably now exceed the benefits, particularly because rheumatic complaints have not been controlled and alcohol consumption has resumed. Agents such as methotrexate and cyclosporine may reduce inflammatory joint activity in the short term, but evidence of their ability to modify the long-term disease process remains elusive. Close monitoring of the effects of these agents is also required because the toxicities often limit long-term use. R.T. should be referred for physical and occupational therapy, encouraged to exercise regularly, and, if needed, referred for orthotics. An NSAID can be given for symptomatic relief. Sulfasalazine and hydroxychloroquine might be beneficial for mild joint symptoms alone, but the cutaneous manifestations may be controlled with topical agents. Other alternative second-line agents include immunomodulatory agents, anticytokines, TNF-α inhibitors, infliximab, and etanercept. In the case of R.T., it is clear that better therapies for PsA are necessary.

Immunomodulatory Agents

With advances in biotechnology immunomodulatory therapy, important treatment alternatives are becoming available for moderate-to-severe plaque psoriasis and PsA that is resistant to other systemic therapies. These agents are thought to target the immune-mediated and elevated levels of TNF found in psoriasis.

MONOCLONAL ANTIBODIES AND TNF-α INHIBITORS: INFLIXIMAB, ETANERCEPT, ADALIMUMAB, GOLIMUMAB, USTEKINUMAB, SECUKINUMAB, and IXEKIZUMAB

As a potent cytokine, TNF-α is involved in inflammation and joint damage. Inhibition of TNF-α reduces direct actions as well as the action of other proinflammatory cytokines. The TNF-α inhibitors,

---

infliximab, etanercept, and adalimumab, are FDA approved for the treatment of both plaque and PsA. Golimumab is approved only for PsA. Ustekinumab is approved for both psoriasis and PsA, whereas secukinumab is currently approved only for plaque psoriasis. The mechanism of action of these agents is through blocking the interaction of TNF-α with cell-surface TNF receptors.[95] Ustekinumab is a specific inhibitor of interleukin-12 (IL-12) and anti-interleukin-23 (IL-23).[95] Secukinumab and ixekizumab inhibit interleukin-17A. Dosing is either subcutaneous injection or intravenous infusion (infliximab), on a biweekly, weekly, every other week, or monthly schedule during the initiation phase.

In a 24-week trial to assess the efficacy and safety of etanercept 50 mg administered once weekly in patients with moderate-to-severe plaque psoriasis, at week 12, 37.5% of patients achieved a PASI 75 response, with 71.1% achieving PASI 75 at week 24. No deaths, serious infections, opportunistic infections, demyelinating disorders, or malignancies were reported.[96] Antibody production has been reported in up to 18% of patients; however, they do not impact the efficacy of etanercept.[97]

Infliximab is a human/mouse chimeric anti-TNF-α antibody. One hundred eighty-six patients were given infliximab for moderate-to-severe plaque and nail psoriasis for 46 weeks. A PASI of 75 was demonstrated in 74.6% of patients, and a PASI of 90 was demonstrated in 54.1% at week 50.[98] In spite of clinically significant improvements, induction of antinuclear antibodies and anti–double-stranded DNA antibodies is frequently observed in patients receiving infliximab. To investigate the development of autoimmunity in patients receiving infliximab for severe, recalcitrant forms of psoriasis, 28 patients with psoriasis refractory to three or more systemic treatments were given infliximab 5 mg/kg for 22 weeks.[99] Detection of antinuclear antibodies and of IgM and IgG anti–double-stranded DNA antibodies was performed at baseline and at week 22. The prevalence of positive detection of antinuclear antibodies increased from 12% at baseline to 72% at week 22 and was also observed for IgM anti–double-stranded DNA antibodies. Three patients exhibited nonerosive polyarthritis, without any other criteria for systemic lupus. This study suggests that the incidence of biologic autoimmunity is high in patients with refractory psoriasis receiving infliximab.[99]

In a 52-week trial to assess the efficacy and safety of adalimumab 80 mg load followed by 40 mg administered every other week in patients with psoriasis, at week 16, 71% achieved an improved PASI score. Only 5% of patients continued on adalimumab until week 52 lost response to adalimumab.[100] Antibody formation for adalimumab, a human monoclonal antibody, occurs in up to 50% of patients, which may reduce the efficacy of this medication.[97]

In phase 3 trials, ixekizumab was superior to etanercept for mild-to-moderate psoriasis. By 12 weeks of ixekizumab dosed every other week, 90% of patients achieved a PASI of 75% versus 48% with etanercept. The most common adverse reactions were infection (26%) and injection site reactions (10%).[101]

Pharmacotherapy with TNF-α inhibitors has the best ratio of number-needed-to-treat-to-benefit (NNTB) to number-needed-to-harm (NNTH) of all disease-modifying antirheumatic drugs (DMARDs) in psoriatic arthritis, and is able to induce clinical remission in at least 30% of patients. Of interest, however, is that in many of these clinical studies, the NNTB presented comparisons with placebo. Many studies of TNF-α inhibitor therapies have allowed inclusion of patients who had not received other systemic therapies beyond topical therapies alone.[102] When interpreting the NNTB for TNF-α inhibitors, it is important to compare them with the NNTB for other systemic therapies. Also, having a comparable outcome measure (e.g., PASI 75) is necessary, especially because most established treatments have not been compared with placebo.[103] To determine which TNF-α inhibitor to use in a patient, consider the results from three meta-analyses. Infliximab was most likely to achieve a PASI of 75. Also, ustekinumab and adalimumab achieve significantly higher PASI 75 scores than etanercept. It is important to note this evaluation was based on 16 weeks of therapy.[104–106]

For a patient like R.T., whose disease cannot be treated successfully or safely with methotrexate, proceeding with a TNF-α inhibitor remains an option. These agents produce rapid, well-tolerated, beneficial responses compared with placebo. Benefit is seen anywhere from 2 to 12 weeks, with a PASI 75 being obtained in at least 80% of patients after 10 weeks of infliximab, at least 50% after 12 weeks of etanercept, and at least 50% after 48 weeks of adalimumab treatment.[107,108] R.T. does not have any contraindications to therapy, such as active infection or New York Heart Association (NYHA) class III or IV heart failure. If available, etanercept (25–50 mg subcutaneously twice weekly [3 or 4 days apart] for the first 3 months, followed by 50 mg once a week) may be preferred for convenience; however, in a recent comparative trial of ustekinumab (administered at weeks 0 and 4) and etanercept (administered twice weekly for 12 weeks), ustekinumab patients experienced a superior improvement in PASI 75 scores.[109]

Screening for tuberculosis before beginning therapy with anti-TNF agents is prudent, and those with evidence of prior tuberculous chest infection or with a positive skin test for tuberculosis should be offered prophylactic antitubercular therapy.

Phosphodiesterase 4 (PDE4) Inhibitors

Apremilast was recently approved by the FDA for the treatment of active PsA because clinical trials demonstrated moderate efficacy in the reduction of symptoms of PsA, including tender and swollen joints. Results from both phase II and phase III clinical trials demonstrated improvement in symptoms, quality of life, and pain in patients randomized to apremilast compared with placebo.[110] Of the patients enrolled in the phase III clinical studies, over half received concomitant therapy with DMARDS (e.g., methotrexate) and 10% to 15% had failed therapy with TNF-α inhibitors.[111]

Dosing is similar to that of plaque psoriasis, a titration up to 30 mg twice daily. The most common adverse effects reported in the clinical trials were gastrointestinal (i.e., diarrhea, nausea), fatigue, headache, and nasopharyngitis. The gastrointestinal adverse events were transient in nature and often occurred early on in therapy.[85]

Combination Therapy

The National Psoriasis Foundation recommendations for combination treatments include methotrexate and a TNF-α inhibitor (etanercept or infliximab), acitretin and infliximab, then a TNF-α inhibitor (etanercept or adalimumab) and phototherapy.[112] There is no evidence as yet to support using two biologics or a biologic with cyclosporine.[112]

Photosensitivity, Photoaging, and Burn Injuries

Katherine G. Moore, Molly E. Howard, and Timothy J. Ives

CORE PRINCIPLES	CHAPTER CASES
PHOTOSENSITIVITY	
1 Ultraviolet radiation (UVR) exposure has been linked to many adverse effects, including malignant melanoma.	**Case 42-1 (Questions 1, 2)**
2 Photoprotection encompasses all methods of UVR blocking, including sunscreens, protective clothing, and sunglasses. Sunscreens are widely used to prevent sunburn and reduce the incidence of premature aging and carcinogenesis, although clothing and avoiding direct sunlight offer greater protection.	**Case 42-1 (Questions 3–9)**
3 The use of tanning beds that use artificial ultraviolet A (UVA) has not been shown to reduce long-term damage to the skin or to provide protection from natural UVR. The use of tanning beds should be minimized, and adherence to Food and Drug Administration (FDA) recommendations on length of exposure should be encouraged.	**Case 42-2 (Questions 1, 2)**
4 Sunburn is a self-limiting condition, which is generally managed with symptomatic treatment including oral analgesics, topical analgesics, and topical anesthetics. Treatment beyond self-management is necessary if the sunburn is accompanied by constitutional symptoms, involves second- or third-degree burns, or is infected.	**Case 42-3 (Question 1)**
5 Phototoxicity and photoallergy are often drug- or chemical-induced reactions to UVR exposure and account for up to 8% of adverse drug reactions.	**Case 42-4 (Questions 1–3)**
PHOTOAGING	
1 Photodamaged skin is characterized as being wrinkled, yellowed, and sagging.	**Case 42-5 (Question 1)**
2 Topical retinoid therapy is most effective for patients of 50 to 70 years of age with moderate-to-severe photoaging and for prophylactic use in patients undergoing the initial changes of photoaging.	**Case 42-5 (Questions 2–5)**
BURN INJURIES	
1 Most burn injuries are minor and can be managed in ambulatory settings.	**Case 42-6 (Question 1)**

② Major second- or third-degree burns should be immediately triaged to a health system with a multidisciplinary team that can adequately manage all of the potential complications.	**Case 42-6 (Question 1)**
③ Synthetic dressings and skin substitutes have expanded the options and the desired outcomes for recovery.	**Case 42-6 (Question 2)**

ULTRAVIOLET RADIATION (UVR) EXPOSURE

Incidence, Prevalence, and Epidemiology

Changing lifestyles have considerably increased human exposure to sunlight: more outdoor recreational activities, more emphasis on tanning, longer life spans, seasonal population shifts to the Sunbelt, and an emphasis on improving vitamin D deficiency. Epidemiologic evidence clearly implicates sunlight as a causative factor in many skin diseases, and public attitudes toward tanning and sun exposure have slowly begun to change. Skin cancer is the most common of all cancers and yet also one of the most preventable. Squamous cell carcinoma (SCC) and basal cell carcinoma (BCC), which together account for more than half of all malignancies in the United States, are linked closely to exposure to ultraviolet radiation (UVR).[1] Melanoma incidence rates have doubled from 1982 to 2011 in the United States, with 65,647 cases in 2011 and 9,128 deaths. Without intervention, the annual cost of treating newly diagnosed melanomas is projected to triple by 2030, but the CDC estimates that a comprehensive national skin cancer prevention program could potentially avert 230,000 melanoma cases.[2] In July 2014, the acting Surgeon General delivered “The Surgeon General’s Call to Action to Prevent Skin Cancer.” The purpose of the call was to unite various sectors of the nation to address skin cancer as a major public health problem, increase awareness of skin cancer, and call for action to reduce risk.[3]

Sunburn, photoaging, immunologic changes in the skin, cataracts, photodermatoses, phototoxicity, and photoallergy are other commonly encountered photosensitivity reactions that occur after UVR exposure. Phototoxicity and photoallergy are often drug- or chemical-induced reactions to UVR exposure and account for up to 8% of adverse drug reactions.[4] The appropriate use of sunscreens or other photoprotective behaviors can help mitigate the incidence of the adverse effects of UVR. Despite this fact, sunscreen use remains low, with recent survey-based estimates showing that fewer than 15% of men and 30% of women use sunscreen on both the face and the exposed skin as recommended. Forty-two percent of men reported never using sunscreen at all.[5]

Etiology

ULTRAVIOLET RADIATION SPECTRUM

Ultraviolet radiation, the primary inducer of photosensitivity reactions in humans, is divided into ranges according to the effects of four primary wavelengths: UVA1 (340–400 nm), UVA2 (320–340 nm), UVB (290–320 nm), and UVC (200–290 nm) (Fig. 42-1; Table 42-1). UVA, with a wavelength of 320 to 400 nm, is closest in wavelength to visible light.[6] UVA radiation levels have small fluctuations during the day and are present from sunrise to sunset every day, all year round, even in the winter and on cloudy days. UVA is considerably less likely than a comparable dose of UVB to cause a similar degree of erythema.[7,8] In contrast to UVB, UVA penetrates into the dermal layer and may cause harmful effects not caused by UVB.[5] About 10 to 100 times more UVA reaches the earth's surface than UVB. Consequently, UVA may contribute up to 15% of the erythemal response at midday.[6,9] UVB is the most erythemogenic and melanogenic of the three UVR bands.[6,10] Up to 90% of UVB is blocked by the earth's stratospheric ozone layer, and it is absorbed completely by the epidermal layer of the skin.[11,12] In addition, UVB radiation can alter the immune system,[12] thereby increasing the incidence of certain cancers, including skin cancers. The only known beneficial effect of UVR in humans is exposure to small amounts of UVB, most commonly through sunlight, which converts 7-dehydrocholesterol to cholecalciferol (vitamin D_3). Vitamin D enhances calcium homeostasis and has direct and indirect effects on cells involved with bone remodeling. As a result, vitamin D can decrease the risk of rickets in childhood and fractures and osteomalacia in adults.[13]

The UVC wavelengths are absorbed completely by the earth's stratospheric ozone layer. Artificial sources of UVC have been used in the sterilization and preservation of food and in minimizing bacterial growth in laboratories and hospital operating rooms by germicidal lamps, which can cause erythema or cataracts if mishandled.[6,10]

ENVIRONMENTAL EFFECTS ON UVR

Ozone and Chlorofluorocarbons

The amount of UVR that reaches the earth's surface is influenced by many factors. Concern has been focused on the implications of depletion of the ozone layer caused by man-made pollutants such as chlorofluorocarbons (CFCs), nitrous oxide, and other greenhouse gases (GHGs).[9,14] In the decade after this effect was first detected in 1983, ozone levels above the Antarctic had fallen to 50% of normal.[14] In the early 1990s, worldwide estimates from the Environmental Protection Agency (EPA) predicted that for every 1% decrease in ozone, UVB radiation reaching the earth's surface would increase by 2% per year, possibly resulting in a 1% to 3% increase per year in nonmelanoma skin cancer.[15] However, further research is needed to determine whether this prediction has been realized.[16] As GHGs contribute to ozone depletion, and because UVA is only slightly filtered by the ozone layer, any decrease in the ozone layer would result in a disproportionate increase in UVB reaching the earth.

Table 42-1

Types of Ultraviolet Radiation and Characteristics

Radiation	Wavelength (nm)	Characteristics
UVA1 (long UVA; long-wave radiation)	340–400	Not absorbed by the ozone layer Passes through glass Produces some tanning, photoaging, and skin cancers Lower carcinogenic potential than UVA2, but harmful over long-term exposure Levels remain relatively constant throughout the day

UVA2 (short UVA)	320–340	Similar characteristics to UVA1, but greater carcinogenic potential with erythema production similar to UVB
UVB (sunburn range of radiation)	290–320	Partially absorbed by the ozone layer before reaching earth Does not pass through glass Causes erythema, sunburn, tanning, wrinkling, photoaging, skin cancers Daily and seasonal variation, with highest intensity at noon

Time of Day, Cloud Cover, and Surface Reflection

The time of day influences the amount of UVR reaching the earth's surface; 20% to 30% of the total daily UVR is received from 11 AM to 1 PM, with 75% between 9 AM and 3 PM. Cloud cover can decrease UV intensity by 10% to 80% and decreases infrared radiation to an even greater extent. This greater attenuation of infrared radiation by cloud cover can lead to an increased risk of UVR overexposure because less infrared radiation will be absorbed by the body and transformed into heat, resulting in less warning of overexposure to UVR. In general, whenever someone's shadow is shorter than his or her height, care should be taken; the shorter the shadow, the more likely a sunburn will occur. Reflection of UVR by substances (e.g., sand, water, snow) also may be important. For example, sand reflects about 25% of incident UVB radiation; therefore, sitting under an umbrella at the beach may not offer adequate protection. Fresh snow can reflect 50% to 95% of incident sunlight. Water reflects approximately 5% of erythemal UVR, whereas 75% of the radiation is transmitted through 2 m of water, offering swimmers little protection.[6] Seasonal changes, geographic latitude, and altitude also influence the amount of UVR reaching the earth's surface.

UV Index

The UV Index/Global UV Index (**http://www.epa.gov/sunwise/uvindex.html**), developed by the EPA, the National Weather Service, and the Centers for Disease Control and Prevention, is a public health education service that is calculated on a next-day basis for every ZIP code across the United States, and worldwide.[17] This index, with a scale from 1 (low exposure) to 11+ (extremely high exposure), forecasts the probable intensity of skin-damaging UVR expected to reach the surface during the noon hour when the sun is highest in the sky. Theoretically, the UV Index can range from 0 (e.g., during the night) to 15 or 16 (in the tropics at high elevations under clear skies). The higher the UV Index, the greater the dose received of skin- and eye-damaging UVR, and the less time it takes before skin damage occurs.

The amount of UVR exposure needed to damage an individual's skin is affected by the elevation of the sun in the sky, the amount of ozone in the stratosphere, and the amount of clouds present. Clear skies transmit 100% of UVR to the earth's surface, with scattered clouds transmitting 89%, broken clouds, 73%, and overcast clouds, 32%. The darker an individual’s skin tone, the longer (or the more UVR) it takes to cause erythema.

Pathophysiology

ERYTHEMA, SUNBURN, AND TANNING

Erythema and Oxygen Free Radicals

Excessive exposure of the epidermal and dermal layers of the skin to UVR can result in an inflammatory erythematous reaction. Excess UVA and UVB cause the release of vasodilatory mediators (e.g., histamine, prostaglandins, cytokines), resulting in increased blood flow, erythema, tissue exudates, swelling, increased sensation of warmth, and a characteristic sunburn.[6,10] Severe UVR exposure, primarily UVB, can cause blister formation, desquamation, fever, chills, weakness, and shock. Erythema caused by UVB begins within 3 to 5 hours after exposure, is maximal after 12 to 24 hours, and usually resolves during the ensuing 3 days.[10] In contrast, erythema caused by UVA begins immediately, plateaus between 6 and 12 hours, and remains for 24 hours. UVA-induced changes in the dermis are characterized by greater damage to the vasculature and dense cellular infiltrates that penetrate to deeper levels of the skin.[10] The dermis also may be damaged when endogenous components of the skin absorb UVR energy and subsequently interact with oxygen to form tissue-damaging oxygen free radicals.[11]

Histology of Sunburn

The skin undergoes adaptive changes in response to UVR exposure.

When keratinocytes in the epidermis are damaged and lose their typical organization, both the epidermis and the stratum corneum thicken and attempt to serve as a barrier to UVR, particularly to UVB.[9] The skin’s normal protective immune response, however, is altered with exposure to UVR. Metalloproteinase proteins act as proteolytic enzymes that are produced from low-dose UVR exposure, causing degradation of collagen and elastin in the dermal matrix.[18] Langerhans cells (i.e., antigen-presenting cells in the skin) are decreased in number and function even after small doses of UVB.[18] These cells abnormally activate suppressor T lymphocytes and lose their ability to activate normal effector pathways of the immune system.[19]

Immediate Pigment Darkening and Delayed Tanning

Tanning is an adaptive mechanism of the skin to UVR. Tanning occurs by two different mechanisms: immediate pigment darkening (Meirowsky phenomenon) and delayed tanning. The primary cell involved in tanning is the melanocyte, which produces the radiation-absorbing protein melanin.[6,9] Immediate pigment darkening begins during the actual exposure to UVA and certain bands of visible light, [6,9] and the oxidation of existing melanin in the epidermis transiently turns the skin grayish brown. The degree of immediate pigment darkening depends on the duration and intensity of exposure, the extent of previous tanning (or amount of preexisting melanin), and the skin type of the individual.[5] Immediate pigment darkening is not protective against UVB erythema.[9]

Delayed tanning occurs 48 to 72 hours after exposure to either UVA or UVB. It is most intense 7 to 10 days after UV exposure and can last for weeks to months.[6] Delayed tanning is the result of increased production of melanin, an increase in the size of dendritic processes, increased melanization of melanosomes, and an increase in the rate of transfer of melanosomes (particulate bodies of melanin) to keratinocytes.[6,9] The keratinocyte, now pigmented with melanosomes, migrates to the epidermis, producing the characteristic suntan. Delayed tanning caused by UVA is less protective against sunburn than delayed tanning caused by UVB, because epidermal thickening is not induced by UVA.[6]

PHOTOCARCINOGENESIS

Squamous Cell and Basal Cell Carcinoma

The association between skin cancer in humans and UVR exposure is based primarily on clinical and epidemiologic evidence. Nonmelanoma skin cancers, such as SCC and BCC, occur most commonly on areas that are maximally exposed to sunlight (e.g., the face, neck, arms, back of the forearms, and hands).[6] The prevalence of nonmelanoma skin cancers is inversely related to geographic distance from the equator and to the melanin content of the skin, with SCC more strongly linked than BCC to UVR.[6,20] Persons of skin types most sensitive to sunlight, as well as persons working outdoors, have higher incidences of nonmelanoma skin cancers.[6] A family history of SCC and BCC increases the risk at least twofold, depending on the histology, number of lesions, and degree of invasiveness.[21] Albinism, a genetic disease characterized by partial or total absence of pigment in the skin, hair, and eyes, is associated with increased and premature development of skin cancers.[6]

Cutaneous Malignant Melanoma

The development of cutaneous malignant melanoma (CMM) also may be linked to UVR exposure, specifically exposures that induce sunburn. A history of five or more severe sunburns during adolescence more than doubles the risk of CMM.[20] Similar to nonmelanoma skin cancers, CMM demonstrates an inverse relationship to geographic distance from the equator and melanin content of the skin.[6] Unlike nonmelanoma skin cancers, however, CMM does not demonstrate a clear relationship to the cumulative dose of UVR, and it occurs on areas of the body exposed to the sun intermittently (e.g., on the back in men and the lower legs in women). In addition, it occurs most commonly in the middle-aged population and in individuals who work indoors, as well as in those whose sun exposure is limited to weekends and vacations.[20] A family history of melanoma is a strong risk factor, as 8% to 12% of melanoma patients display a familial propensity for the disease.[22]

Mechanisms of Carcinogenesis

Mechanisms of carcinogenesis may include damage to DNA and alterations in immunologic status. Epidermal and dermal DNA can absorb UVR, which can contribute to abnormal formation of pyrimidine dimers. Under normal circumstances, these dimers are excised and repaired; however, if left uncorrected, these DNA lesions, as well as an inactivity of p53 tumor suppressor gene activity, can lead to interruption of transcription, with possible mutagenesis and malignancy.[23]

PHOTOEFFECTS ON THE EYE

Exposure to UV radiation can cause many types of ocular adverse effects including cataracts, conjunctival degeneration and proliferation, as well as squamous cell carcinoma of the cornea and conjunctiva.[24] Age-related opacification of the ocular lens, or senescent cataracts, has been attributed to a lifetime of exposure to sunlight. The incidence of cataracts increases steadily after age 50, reaching nearly 30% in individuals older than 74.[25] UVB is absorbed by the cornea and lens, which slowly results in protein oxidation and precipitation within the lens. UVA penetrates the ocular lens and can cause cumulative damage to deeper structures of the eye. Decreased transmittance and increased scattering of light by the opacified lens eventually result in blurred vision, rings or halos around lights, changes in color perception, and blindness.[24] In advanced cases, the only treatment is surgical removal of the cataract.

High exposure of the eye to UVR (which can range from a few seconds of exposure to arc welding, a few minutes of exposure to a UVC-emitting germicidal lamp, commercial tanning, or UVR reflection by snow or sand) can cause conjunctivitis or photokeratitis, a painful inflammation of the cornea. Photokeratitis usually begins 30 minutes to 24 hours after the exposure, and time to onset depends on the intensity of the exposure.[26] Conjunctivitis commonly accompanies photokeratitis and is characterized by the sensation of a foreign body or grit in the eyes. Varying degrees of photophobia, lacrimation, and blepharospasm also may accompany photokeratitis.[26] Because the corneal epithelium has a great regenerative capacity, photokeratitis tends to be transient, with regression in 24 to 48 hours. Treatment consists of cool, wet compresses and mild anti-inflammatory analgesics, such as ibuprofen, aspirin, or naproxen sodium.

PHOTOTOXICITY AND PHOTOALLERGY

The most common type of drug-induced photosensitivity reaction is phototoxicity, which is an immediate or delayed inflammatory reaction that occurs when a compound with photosensitizing ability absorbs a sufficient concentration of UVR in or on the skin, and when the skin is exposed simultaneously to a specific wavelength of light.[27,28] When the offending agent is deposited on the skin surface, it is thought to act as a chromophore, absorbing UVR. When the chromophore reaches a sufficient concentration in or on the skin, and when the skin is exposed to the appropriate wavelength of UVR, energy is emitted and transferred to the surrounding molecules, which damages the adjacent tissue to cause a phototoxic reaction. The wavelength of radiation necessary to produce such a reaction depends on the absorption spectrum of the offending agent.[29]

Photoallergy results from a similar mechanism to phototoxicity, except that the immune system is involved. Most commonly, it is caused by polycyclic photosensitizers that react with UVA to form antigenic macromolecules, evoking a delayed hypersensitivity response. In photoallergic photosensitivity reactions, the suspected medication or chemical agent is altered in the presence of UVR to become antigenic or to become a hapten (i.e., an incomplete antigen), which can combine with a tissue antigen. These antigen–antibody or immune-mediated processes differentiate photoallergic from phototoxic reactions. Photoallergic reactions do not occur on first exposure to the medication, but as with other allergic reactions, they require prior or prolonged exposure (sensitization period) to the offending agent.[27,28] Once sensitization has occurred, subsequent exposure to even small amounts of the offending product will produce a photoallergic reaction.

Photoprotection

Photoprotection encompasses all methods of UVR blocking, including sunscreens, protective clothing, and sunglasses. Sunscreens are widely used to prevent sunburn and reduce the incidence of premature aging and carcinogenesis,[30–32] although clothing and avoiding direct sunlight offer greater protection. Sunburn preventive agents are those active ingredients that absorb greater than 95% of UVB radiation, and have the potential to prevent sunburn. Suntanning agents are those with active ingredients that absorb 85% to 95% of UVB radiation, thereby allowing suntanning without significant sunburn in the average individual. Chemical sunscreens include both of the aforementioned designations. Opaque sunblocks, or physical sunscreens, are those active ingredients that reflect or scatter all UVA, UVB, and visible light, thereby preventing or minimizing sunburn and suntanning.[33] The original formulations were developed to protect against the effects of UVB radiation before adverse effects of UVA were recognized. Because UVA plays a significant role in many of the adverse effects associated with UVR exposure, broad-spectrum sunscreen products with absorption spectra in the UVA range have become commercially available, in combination with UVB absorbers. These broad-spectrum products provide additional benefit for patients with photosensitivity reactions caused by wavelengths not covered by single-ingredient sunscreens. Table 42-2 lists the available sunscreen chemicals that have been judged to be both safe and effective.

There is a clear association between UV exposure and the development of BCC and SCC,[34] and limiting UV exposure by starting sunscreen use during childhood is a key to reduce the lifetime risk of nonmelanoma skin cancers; however, some investigators have suggested that sunscreen use, through increased UV exposure, may actually cause melanoma, perhaps because its use allows for a longer exposure to the sun,[35,36] and because historically there was a lack of UVA protection in most products.[37] Sunscreen use has been thought to be associated with the occurrence of nevi (pigmented moles), an important risk factor for melanoma development[38]; however, epidemiologic analyses have refuted this proposed association, largely on the basis of a longer exposure to UVR and less protective clothing in individuals who developed nevi.[39,40]

Clinical Application of Photosensitivity

SKIN TYPES

CASE 42-1

QUESTION 1: R.J., a 26-year-old woman, and her husband J.J., 28 years old, are spending a week in August vacationing on the Outer Banks of North Carolina with their two children, P.J., a 6-month-old girl, and L.J., an 18-month-old boy. They have plans for time at the beach, bicycling, and sailing. They come to your pharmacy to inquire about sunscreens for the trip. R.J. has a light brown complexion with brown hair and brown eyes, and J.J. has fair complexion with blonde hair and blue eyes. On first exposure to the sun with about an hour of intense midday sunlight, J.J. almost always develops a deep red, painful sunburn, with only minimal subsequent tanning. He freckles easily when exposed to sunlight and remembers being severely sunburned on several occasions as a child. When R.J. is first exposed to the sun in the summer, she usually develops mild erythema, followed by moderate tanning. She cannot recall being severely sunburned as a child, but does recall becoming moderately tanned each summer as a child and adolescent. R.J. is employed as a receptionist for an accounting firm, and J.J. is a lawyer for a local law firm. Both spend considerable amounts of time participating in outdoor activities. Using subjective and objective data in this history, determine the skin types of R.J. and J.J. to guide you to a recommendation of a sunscreen product.

Table 42-2

Sunscreens and UVR Absorption

Sunscreen	Absorption
Anthranilates	

Meradimate (menthyl anthranilate)	260–380
Benzophenones	
Dioxybenzone	250–390
Oxybenzone (benzophenone-3)	270–350
Sulisobenzone (Eusolex 4360)	260–375
Cinnamates	
Cinoxate (diethanolamine p-methoxycinnamate)	280–310
Octocrylene	250–360
Octinoxate (octyl methoxycinnamate, Parsol MCX)	290–320
Dibenzoylmethanes	
Avobenzone (butyl methoxydibenzoylmethane, Parsol 1789)	320–400
Aminobenzoic Acid and Ester Derivatives	
Para-aminobenzoic acid (PABA)	260–313
Padimate O (octyl dimethyl PABA)	290–315
Salicylates	
Homosalate	295–315
Octisalate (octyl salicylate)	280–320
Trolamine salicylate	260–320
Camphor Derivatives	
Ecamsule (terephthalylidene dicamphor sulfonic acid; Mexoryl)	290–400
Others	
Ensulizole (phenylbenzimidazole sulfonic acid)	290–340
Physical Sunscreens	
Titanium dioxide	290–700
Zinc oxide	290–700

UVR, ultraviolet radiation.

One of the most important pieces of information to include in the patient history is the patient's skin type.[41] Patients can be classified into six sun-reactive skin types based on their response to initial sun exposure, skin color, tendency to sunburn, ability to tan, and personal history of sunburn (Table 42-3). This skin typing system is used by the US Food and Drug Administration (FDA) in its guidelines for sunscreen agents. J.J.'s fair complexion, propensity to sunburn, and minimal tanning classify him as skin type II. R.J.'s light brown complexion, minimal sunburn reaction, and moderate tanning classify her as skin type IV.

Hair and eye colors also provide an indication to skin reactiveness to sunlight. People who have blonde, red, or light brown hair or blue or green eyes tend to have greater skin reactivity to sunlight than people with dark-colored hair or eyes. A history of severe sunburn also can be associated with skin reactivity to sunlight, although self-reported patient histories of sunburn or tanning may not be consistently reliable and personal interviews may be a better indicator. J.J.'s propensity to freckle and his history of severe sunburns as a child may give an indication as to his skin's sun reactiveness. Other important information to consider in the patient before recommending a certain product is medication history, history of sun-reactive dermatoses, history of allergies (particularly contact hypersensitivities to cosmetics or other topical agents), and the intended activities during sunscreen use.

RISK FACTORS

CASE 42-1, QUESTION 2: R.J. and J.J. exhibit several risk factors that place them at risk for the long-term adverse effects of UVR. What are the risk factors for these long-term adverse effects of UVR?

The long-term effects of UVR include photocarcinogenesis and premature aging of the skin (photoaging). The associated risks for the development of these long-term effects are directly related to the congenital pigmentation of an individual (which includes skin type and hair and eye color) and intensity, duration, and frequency of exposure to UVR. With skin type II, J.J. is at high risk for carcinogenesis and photoaging, whereas R.J., with skin type IV, may be at a lower risk. Excessive sun exposure, especially during early childhood, increases the risk of nonmelanoma and melanoma skin cancers. During the first 18 years of life, the average child receives 3 times the dose of UVB of the average adult; consequently, most sun exposure occurs during childhood.[23,42,43] A history of frequent sunburn or intermittent high-intensity exposures to UVR may be associated with the occurrence of malignant melanoma, whereas large cumulative doses of UVR during a lifetime may contribute to the incidence of nonmelanoma skin cancers. J.J.'s history of several severe sunburns as a child may more than double his risk of CMM.[42,43] Cumulative doses of UVR received unintentionally from working outdoors or from participating in outdoor recreational activities also can contribute significantly to the risk of photocarcinogenesis and photoaging.[7] A large number of moles, congenital moles more than 1.5 cm wide, and abnormal moles also appear to be a risk factor for malignant melanoma.[20] Risk for skin cancer is increased among first-degree relatives of patients with skin cancer[44] because frequent sunburns, suboptimal sunscreen use, and high rates of tanning bed use are common among children with a personal or family history of skin cancer.[45]

Photoprotection

Sun Protection Factor

CASE 42-1, QUESTION 3: Before deciding on the exact product for R.J., J.J., and their children, R.J. and J.J. want to know how to differentiate among products and how to interpret the SPF of a product. How will you explain this to them?

The effectiveness of a sunscreen formulation is based on its SPF and its substantivity.[46] SPF is a measure of how much solar energy (UV radiation) is required to produce sunburn on protected skin (i.e., in the presence of sunscreen) relative to the amount of solar energy required to produce sunburn on unprotected skin. Because the SPF value increases, sunburn protection increases. It is defined as the ratio of the minimal dose of UVR required to produce an erythemal response in sunscreen-protected skin compared with unprotected skin.[30] The SPF is based on tests of volunteers with skin types I through III, using either natural sunlight or a solar simulator that generates both UVB and UVA.[30,46] Because the SPF can be influenced by the composition, chemical properties, emollient properties, and pH of the vehicle, sunscreen formulations must be evaluated on an individual basis.[46] The concept of a SPF is commonly misunderstood and is also influenced by a variety of factors including the amount applied to the skin, the time of initial application before UVR exposure, the frequency of application, and environmental factors, such as photodegradation during UVR exposure; therefore, the SPF achieved during actual use can be significantly less than indicated on the label.[47–51] Consumers have been shown to routinely apply only one-fourth to one-half thickness of the layer of sunscreen used to determine the SPF before marketing.[52–55]

A popular misconception is that SPF relates to time of solar exposure. For example, many people believe that if they normally get sunburn in 1 hour, then an SPF 15 sunscreen allows them to stay in the sun for 15 hours (i.e., 15 times longer) without getting sunburn. This is untrue because SPF is not directly related to time of solar exposure, but to the amount of solar exposure. Although solar energy amount is related to solar exposure time, other factors have an impact on the amount of solar energy. For example, the intensity of the solar energy has an impact on the amount. Generally, it takes less time to be exposed to the same amount of solar energy at midday compared with early morning or late evening because the sun is more intense at midday relative to other times. The following exposures may result in the same amount of solar energy: one hour at 9 AM versus 15 minutes at 1 PM. Solar intensity is also related to geographic location, with greater solar intensity occurring at lower latitudes. Also, because clouds absorb solar energy, solar intensity is generally greater on clear days than on cloudy days.

Table 42-3

Suggested SPF for Various Skin Types

Complexion	Skin Type	Skin Characteristics	Suggested Product SPF
Very fair	I	Always burns easily; never tans	20–30
Fair	II	Always burns easily; tans minimally	15–20
Light	III	Burns moderately; tans gradually	10–15
Medium	IV	Burns minimally; always tans well	8–10

Dark	V	Rarely burns; tans profusely	8
Very dark	VI	Never burns; deeply pigmented	8

SPF, sun protection factor.

In 1978, the FDA Over-the-Counter (OTC) Review Panel on sunscreens reclassified sunscreens from cosmetics to drugs intended to protect the structure and function of the human integument against actinic damage. In 1999, the FDA finalized its original regulations for OTC sunscreens (available at: **http://www.fda.gov/downloads/Drugs/DevelopmentApprovalProcess/Developme the-CounterOTCDrugs/Statusof-OTCRulemakings/ucm090244.pdf**). The 1999 regulations listed the active ingredients that can be used in sunscreens as well as labeling and testing requirements. They also provide for uniform, streamlined labeling for all OTC products intended for use as sunscreens to assist consumers in making decisions on sun protection.

Additionally, cosmetic regulations required tanning preparations that do not contain a sunscreen ingredient to display the following warning: “Warning—this product does not contain a sunscreen and does not protect against sunburn. Repeated exposure of unprotected skin while tanning may increase the risk of skin aging, skin cancer, and other harmful effects to the skin even if you do not burn.”

In 2006, the FDA introduced further regulations on sunscreen labeling. The term sunscreen was redefined: “A product with active ingredients to affect the structure or function of the body by absorbing, reflecting, or scattering the harmful, burning rays of the sun, thereby altering the normal physiological response to solar radiation.” These ingredients also help to prevent diseases such as sunburn and may reduce the chance of premature skin aging, skin cancer, and other harmful effects attributable to the sun when used in conjunction with limiting sun exposure and wearing protective clothing. Sunscreen ingredients may also be used in some products for nontherapeutic, nonphysiologic uses (e.g., as a color additive or to protect the color of the product).

In 2007, the FDA proposed a new amendment to its original regulations, which sets standards for formulating, testing, and labeling sunscreen products.[56] The final rule, which did not take effect until June of 2012, limited the maximum SPF value on sunscreen labeling to “SPF 50+,” as well as establishing that claims of water resistance must tell how much time a user can expect to receive the stated level of SPF protection while sweating or swimming, based on standard testing.[57] Claims of products being “waterproof” or “sweatproof” are no longer allowed, nor can products be identified as “sunblocks.” Qualifications for products to be labeled as “broad spectrum” were standardized and must provide protection against both UVA and UVB radiation. Additional warnings about skin cancer and skin aging were added to products that were not broad spectrum or have low SPF ratings <15. The SPF maximum of 50+ resulted due to the lack of data that SPF levels higher than 50 provide any additional benefit.[57] Despite this new regulation, products listed with SPF >50 are still available for purchase.

In November 2014, the Sunscreen Innovation Act (SIA) was enacted, which provided a new process for the FDA review of the efficacy and safety of nonprescription sunscreen active ingredients.[58] The act amended the Food, Drug, and Cosmetic Act to provide specific timelines and deadlines requiring FDA review of time and extent applications (TEAs) for sunscreen ingredients. This helps to ensure that timely decisions are made on ingredients that had been pending review.[58,59] In response to the SIA in early 2015, the FDA made tentative determinations on eight ingredients that had been pending review, including bemotrizinol, bisoctrizole, drometrizole trisiloxane, octyl triazone, amiloxate, diethylhexylbutamido triazone, ecamsule, and enzacamene. These ingredients were found to have insufficient evidence of safety and effectiveness at the concentrations in question and are in need of more data to determine whether they are generally recognized as safe and effective (GRASE) for use in over-the-counter sunscreen products.[60]

Evaluation of Sunscreens

Substantivity is a measure of the sunscreen formulation's effectiveness. The substantivity of a sunscreen formulation is its ability to be absorbed by, or adhere to, the skin while swimming or perspiring. The substantivity of a product largely depends on the vehicle, as well as the active ingredient.[61] The affinity of a sunscreen to the keratinaceous layer of the stratum corneum is directly related to the keratin or vehicle partition coefficient. The saturation of the active agent in keratin depends on the drug's lipophilicity, whereas its substantivity is independent of its lipophilicity. Sunscreen compounds with a high solubility in the product's vehicle penetrate the skin most easily. Classically, vehicles such as water-in-oil emulsions or ointments tend to have a higher degree of substantivity. Some of the newer products have improved substantivity with the addition of a polymer, such as polyacrylamide, to the formulation.

Molar Absorptivity, Absorption Spectrum, and Photostability

The molar absorptivity and absorption spectrum determine the effectiveness of an individual sunscreen agent, mostly by its chemical structure. Molar absorptivity is a measure of the amount of UVR absorbed by a particular sunscreen, and it depends on the concentration of the sunscreen in the product and the amount applied to the skin. Sunscreens with an absorption spectrum in the UVB range, with a maximal absorption between 310 and 320 nm, are the most effective in preventing a sunburn.[46] Sunscreens with absorption spectra in the UVB range are para-aminobenzoic acid (PABA) and its esters, cinnamates, and the salicylates. Sunscreens with absorption spectra that extend into the UVA range are the anthranilates (e.g., meradimate), dibenzoylmethanes (e.g., azobenzene), and benzophenones (e.g., oxybenzone). Photostability means the ability to stabilize under sunlight. The process of photostability is a key factor in sunscreen protection efficacy. High photostability means the sunscreen will maintain a higher UVA protective barrier longer and not degrade as quickly as other UVA filters when exposed to the sun.

Table 42-2 shows the 17 ingredients that act as sunscreens currently approved in the United States, along with their FDA-allowable maximal concentration and absorption spectrum.

CHEMICAL ORGANIC SUNSCREENS

Chemical organic sunscreens are compounds capable of absorbing UVR, thereby protecting the skin structures from the adverse effects of the selective wavelengths absorbed.[30] After application to the skin, these aromatic compounds convert the high UVR energy into harmless longer-wave radiation, which may or may not be perceived as warmth.[30] Chemical organic sunscreens usually are nonopaque because they do not absorb the wavelengths of visible light.

UVB Filters

Aminobenzoates

Commonly used in the past and the first widely used UV filter, PABA absorbs UVR in the UVB range from 260 to 313 nm, with maximal absorption around 290 nm; its molar absorptivity is considered to be high.[46] PABA readily penetrates and binds to the stratum corneum and, after several days of application, may remain in the skin and provide protection even after swimming, perspiration, and bathing, making it an ideal candidate for water-resistant sunscreens.[46] It is commonly formulated as an alcoholic mixture, which can cause stinging, dryness, or tightness, particularly when applied to the face. Its major disadvantage is the potential to cause contact or photocontact dermatitis, which has been reported to happen in approximately 4% of the population.[62] Responsible for more sensitivity reactions than any other sunscreen,[49] PABA can also cause cross-sensitivity reactions with benzocaine, thiazides, sulfonamides, paraphenylenediamine (a common ingredient in hair dyes), and other PABA derivatives. It can cause discoloration of clothes as well. The use of PABA in commercial sunscreens has decreased to the point where many of the newer sunscreens are promoted as being PABA-free.

The PABA esters include octyldimethyl PABA (Padimate O) and glyceryl PABA. These esters are incorporated easily into formulations, demonstrate good substantivity, and do not discolor clothing. Their absorption spectra are similar to those of PABA (Table 42-2). With a maximal absorption of 311 nm, Padimate O has the lowest likelihood of any PABA ester to cause cross-sensitivity reactions or contact and photocontact dermatitis.[63]

Cinnamates

Octinoxate (octyl methoxycinnamate), which has high molar absorptivity and a maximal absorption of 305 nm, is the most commonly used cinnamate and most potent UVB filter.[64] Cinnamates are related chemically to balsam of Peru, balsam of Tolu, coca leaves, cinnamic acid, cinnamic aldehyde, and cinnamic oil, ingredients that are used in perfumes, topical medications, cosmetics, and flavorings.[65] These agents do not bind well to the stratum corneum, leading to poor substantivity. Cinnamate-based sunscreens tend to be comedogenic because the vehicle may contain other occlusive ingredients that are added to improve the substantivity. Cinnamates are often used in combination with benzophenones, appear to be nonstaining, and rarely cause contact dermatitis.[64]

Salicylates

Salicylates are weak UVB absorbers often found in PABA-free products. Topical salicylates are considered among the safest sunscreens, even though they must be used in high concentrations to meet the SPF requirement.[66] Salicylates have low molar absorptivities, are incorporated easily into formulations, and are used to boost the SPF of combination products, particularly oxybenzone and avobenzone.[67] Octisalate and homosalate are water insoluble, which leads to high substantivity. Sensitization to the salicylates is rare[66]; however, it has been reported with the use of octisalate.[68]

Octocrylene

Octocrylene has a absorption profile similar to the salicylates and cinnamates, with a peak absorption at 307 nm. It has low irritation potential and low substantivity; however, it has become increasingly popular because of its ability to photostabilize avobenzone.[69]

UVA Filters

Benzophenones

Benzophenones, such as oxybenzone and dioxybenzone, are UVB-absorbing sunscreens that have absorption spectra extending into the UVA range.[70] Benzophenones are also found in shampoos, soaps, hair sprays and dyes, paints, varnishes, and lacquers. The maximal absorption for each is about 290 nm, but both are limited because of poor substantivity and sensitization.[70] Photocontact dermatitis with oxybenzone and contact dermatitis with dioxybenzone occur commonly, with the latter usually occurring as a contact urticaria.[71] Systemic absorption has also been noted with oxybenzone, and it can be detected in the urine and bloodstream.[72]

Anthranilates

Anthranilates, such as meradimate (menthyl anthranilate), are weak UVB-absorbing sunscreens with an absorption spectrum extending into the UVA range. As with the salicylates, they have low molar absorptivity, with a maximal absorption of approximately 336 nm.[46] Meradimate has a low risk of sensitization and a desirable absorption spectrum, especially when it is used in combination with other sunscreens to give broad-spectrum protection.

Dibenzoylmethanes

As a prototype of the dibenzoylmethane class, avobenzone (butyl methoxydibenzoylmethane) has high molar absorptivity and absorption spectra exclusively in the UVA range, with maximal absorption at approximately 360 nm. [73] It is commonly formulated with UVB sunscreens to broaden UVR coverage. Avobenzone loses approximately 35% of its absorption capacity about 15 minutes after UVR exposure, because of the photoinstability of the compound, thereby reducing its UVA protection efficacy. [74] One molecule of avobenzone can absorb UVA radiation only once, making it inactive from that time forward as opposed to zinc oxide or titanium dioxide, which can reflect UVA radiation over and over again with minimal decay. All of the avobenzone applied to the skin is virtually rendered inactive after 5 hours of UVA exposure. Avobenzone is also not compatible with octinoxate, the most powerful UVB filter.[75] Photostability of avobenzone can be increased with the use of UV absorbers, as well as non-UV filters. Neutrogena has marketed this technology under the name of Helioplex, which initially stabilized avobenzone using oxybenzone and diethylhexyl 2,6-naphthalate (DEHN), but has now broadened to include additional technologies and ingredients.

Ecamsule

Ecamsule is a camphor derivative that protects against short UVA rays and is photostable and water resistant, and has low systemic absorption.[76] The FDA has only approved ecamsule for use in certain formulations such as the combination of 2% ecamsule/2% avobenzone/10% octocrylene cream (Anthelios SX, L'Oreal USA). This OTC product is only available in the United States as a moisturizing cream with an SPF rating of 15, with the FDA determining that more research was needed to evaluate the safety and efficacy of ecamsule in other concentrations.[60] This combination provides continuous protection across most of the UV spectrum (290–400 nm range), with ecamsule providing protection within the short UVA range (320–340 nm), filling the gap between octocrylene and avobenzone capabilities (210–290 nm, and 340–400 nm, respectively). The photostability of the ecamsule and octocrylene–avobenzone combination provides residual protection at 1 and 5 hours (1 hour, 100% UVB protection and 97% UVA protection; 5 hours, 90% UVB protection and 80% UVA protection). Adverse events associated with its use are infrequent and include acne, dermatitis, xerosis, eczema, erythema, pruritus, skin discomfort, and sunburn.

There are two additional formulations of ecamsule. Mexoryl SX is a water-soluble form suitable for daytime sunscreens, including sunscreen-containing moisturizers and facial foundations. Mexoryl XL, an oil-soluble formulation, is suitable for water-resistant sunscreen formulations, including those worn on the beach and during vigorous physical exercise.

INORGANIC SUNSCREENS

Inorganic sunscreens are opaque formulations made of particulate insoluble compounds, incorporated into a vehicle, which scatter and absorb UV rays. Both size of the particles and thickness of the film determine the degree of protection.[77] Currently, there are only two inorganic sunscreens approved by the FDA: titanium dioxide and zinc oxide.[77,78] Other inorganic sunscreens include magnesium oxide, red veterinarian petrolatum, iron oxides, kaolin, ichthammol, and talc. Iron oxides and talc continue to be found in commercially available sunscreen products and cosmetics, whereas kaolin and ichthammol may be found in products such as cleansers, moisturizers, and ointments. These compounds are often used in conjunction with chemical sunscreens to formulate products of higher SPF and as single-ingredient products. When used alone, they are usually placed in an ointment base designed specifically for vulnerable parts of the body, such as the nose, cheeks, lips, ears, and shoulders.[33] Inorganic sunscreens are important in individuals who are unusually sensitive to UVA and visible light, such as those with vitiligo, a skin condition with amelanotic lesions (white patches) surrounded by areas of normally pigmented skin. Appropriately colored formulations can be used to camouflage and protect these vulnerable amelanotic lesions.[33] Inorganic sunscreen agents are preferred for persons who need absolute UVR and visible light protection (e.g., young children, persons with skin types I through IV who receive constant exposure, and persons with drug photosensitivity reactions, xeroderma pigmentosa, lupus erythematosus, and other photosensitive skin reactions).[33]

Despite some advantages, inorganic sunscreens are not widely accepted because they are visible to others, messy, and occlusive when applied to the skin. They have a higher substantivity, but may melt in the heat of the sun, limiting their protection to a few hours. Physical sunscreen products tend to be so occlusive that they may cause or worsen acne or obstruct sweat glands.[33] Substantial effort has been made to improve the shortcomings of these products by reducing the particle size to improve the cosmetic appearance. This has created a growing trend toward incorporating nanoparticles of titanium dioxide and zinc oxide, which have been shown to have superior UV protection while maintaining cosmetic elegance. Concern about toxicity of these agents has been raised because of the potential for increased skin penetration and interaction with lower portions of the epidermis; however, this has been disproved in both in vivo and in vitro studies.[79–83] No current regulation in the United States exists regarding the testing and labeling of nanosized titanium or zinc oxides.

Antioxidants

The addition of botanical antioxidants and vitamins C and E to a broad-spectrum sunscreen may further decrease UV-induced damage compared with sunscreen alone due to neutralization of free radicals.[78,84] Antioxidants have received increased attention for use as photoprotective agents, particularly because of the observation that vitamin C levels in the skin can be severely depleted after UVR exposure.[85] Vitamins C and E, either taken orally or applied topically (incorporated into a commercially available sunscreen product), may provide additive protection against both UVA- and UVB-induced photodamage.[85,86] Topically applied antioxidants do not have adequate diffusion into the epidermal layer, however, and are susceptible to chemical instability.[67] If recommended, they should only be used in conjunction with adequate sunscreen. Commercially available products can be found with combinations of antioxidants and broad-spectrum sunscreens, specifically those formulated for facial use.

Given their plans for the week of vacation and amount of UV exposure likely, R.J. and J.J. should consider a broad-spectrum product with high substantivity and a high degree of water resistance to offer the best protection.

CROSS-SENSITIVITY

CASE 42-1, QUESTION 4: According to your assessment of R.J. and J.J., you determine that they have type IV skin and type II skin, respectively. On further inquiry, you learn that R.J. has no medication allergies; however, she has a history of contact dermatitis on her scalp and around her hairline on several occasions after dyeing her hair and using certain shampoos. As a teenager, J.J. suffered from frequent sinus infections and often was treated with trimethoprim–sulfamethoxazole (TMP-SMX) because of an allergy to penicillin. He remembers developing a severe sunburn after minimal exposure to the sun while taking the sulfa-containing antibiotic. He recently has been started on hydrochlorothiazide (HCTZ), 12.5 mg PO daily, for hypertension. What considerations are important in recommending sunscreens for R.J. and J.J.?

The first consideration for recommending an appropriate sunscreen to R.J. and J.J. is their skin type. R.J. has skin type IV, suggesting that a sunscreen with an SPF of at least 15 would provide adequate protection for her (Table 42-3). J.J. has skin type II, suggesting that a sunscreen with an SPF of 30 to 50 would be required to provide adequate protection for him. Furthermore, the history of contact dermatitis and photosensitivity reaction exhibited by R.J. and J.J., respectively, is important when recommending use of a sunscreen.[87] The contact dermatitis that R.J. experienced from hair dyes and shampoos may have been caused by paraphenylenediamine, an ingredient of hair dyes,[88] or a benzophenone, which sometimes is included in products such as hair dyes and shampoos.[70]

Because cross-reactivity between paraphenylenediamine and PABA or its derivatives is possible, a sunscreen for R.J. that does not contain PABA or a benzophenone should be recommended. Cinnamates and anthralates rarely cause contact dermatoses, which would be ideal for R.J.

Because both contain sulfa moieties, the photosensitivity reaction that J.J. experienced while taking TMP-SMX may indicate that he might be susceptible to a cross-sensitivity reaction with PABA or its derivatives. This reaction to TMP-SMX also indicates that J.J. may be susceptible to a photosensitivity reaction with HCTZ. If a photosensitivity reaction is likely, it is advisable to recommend an SPF of 30 or more. Because drug-induced photosensitivity reactions are caused by UVA, a PABA-free, broad-spectrum sunscreen that absorbs UVA as well as UVB would be necessary to provide J.J. with adequate protection. Broad-spectrum chemical sunscreens commonly contain a benzophenone and a cinnamate. A broad-spectrum sunscreen containing both of these chemical classes would be an acceptable broad-spectrum product. Alternatively, because Padimate O is the least likely of the PABA ester derivatives to cause photocontact dermatitis,[63] a broad-spectrum combination product that contains Padimate O could be recommended for J.J. If the photosensitivity reaction is caused by visible light, it would also be necessary to recommend an inorganic physical sunscreen to block all sunlight or complete avoidance of the sun.[50] With all of these issues considered, it may be preferable to recommend an alternative antihypertensive medication for J.J. that would not place him at risk for a photosensitivity reaction.

PHOTOPROTECTION FOR CHILDREN

CASE 42-1, QUESTION 5: What photoprotective measures should be provided for P.J. and L.J.?

Sun protection during childhood is very important, considering that most of a person's lifetime of sun exposure occurs in childhood and that the harmful effects of UVR are cumulative.[38] However, infants and toddlers are at increased risk of over exposure to topical

sunscreen products because of an increased body-surface-area to body-weight ratio compared to adults and a lower ability to metabolize absorbed drug.[89,90] It is therefore recommended that sunscreen should not be used for children younger than 6 months of age.[91] P.J. needs to be kept out of direct sunlight and, when outside, must be protected with proper clothing and shading.[91–95]

L.J. should be protected with a PABA-free, inorganic UV filter sunscreen such as zinc oxide with an SPF of at least 15. Inorganic UV filters are preferred for children between 6 months and 2 years due to lack of systemic absorption.[89,90] Regular use of a sunscreen with an SPF of at least 15 for the first 18 years of life can reduce the lifetime incidence of nonmelanoma skin cancers by about three-fourths.[95] If L.J. is in the sun during 6 hours of maximal exposure (i.e., 10 AM–4 PM), or otherwise for an extended period, he should wear protective clothing, covering as much of his body as possible.[94] Tightly woven clothing, long sleeves, and pants protect the skin from almost all UVR, whereas loosely woven clothing or wet T-shirts can allow up to 30% of UVR to pass through to the skin. Although not complete, water is thought to reduce UVR scattering, thus decreasing its transmission. An average-weight cotton T-shirt provides only an SPF of 7 or 8.[94]

The transmission of UVR through a fabric is measured using a spectrophotometer or spectroradiometer. The ultraviolet protection factor (UPF), rather than SPF, has been recommended as a measure of the sun-protective properties of fabrics.[96,97] It is calculated using a formula based on UV transmission through the fabric and the erythema responsible for human skin. For example, if a fabric has a UPF of 20, then only one-twentieth of the UVR at the surface of the fabric actually passes through it. Certain synthetic fabrics have UPF values that exceed 500, making them vastly superior to sunscreens.[94] Table 42-4 compares the UPF with the amount of effective UVR transmitted and absorbed.

No woven fabric provides complete coverage because the holes between the threads permit UVR transmission. A baseball cap shields little more than the upper central forehead. Broad-brimmed hats can protect the ears, neck, nose, and cheeks, but may provide inadequate protection against SCC of the head or neck.[98] The use of an ultraviolet-absorbing ingredient for fabric softeners (e.g., bisoctrizole, Tinosorb M, BASF) is promoted to reduce transmission of excessive UVA and UVB radiation through fabrics to the skin, through absorption of UV radiation without impairing whiteness. This chemical absorption process has a high affinity for cotton fibers at various washing temperatures. Available as a laundry additive (e.g., Sun Guard, Phoenix Brands), it works by binding to laundered fibers, and through accumulation, it increases the UV protection up to UPF 30 through up to 20 wash and rinse cycles.[99,100]

Product Selection

Two types of sunscreens are appropriate for use in children. A lotion is preferred for total body application versus an alcoholic lotion or gel because alcoholic preparations can cause stinging, burning, and irritation of the skin and eyes. Physical sunscreens (e.g., zinc oxide) are available in bright colors and are recommended for selected body areas, such as the nose, cheeks, and shoulders. PABA and its derivatives are considered potentially harmful to a child’s tender skin. For adolescents with acne vulgaris, the use of an oil-free, noncomedogenic sunscreen formulation (e.g., Neutrogena Clear Face Break-Out Free Liquid-Lotion Sunscreen) and a lip balm that contains a sunscreen of at least SPF 15 (e.g., Blistex or ChapStick Sunblock [SPF 30]) would be appropriate.

Application

CASE 42-1, QUESTION 6: What instructions should you provide R.J. and J.J. on how to apply the sunscreen that you have chosen for each of their family members?

Because R.J. and J.J. are planning to be active on the beach, sunscreens that are water resistant are recommended. Before complete application of the sunscreen to the body, because of the risk of cross-sensitivity reactions, patients can perform a patch test by applying a small quantity of the sunscreen to the inner aspect of the forearm and covering with a small bandage overnight.

Most persons apply 20% to 60% of the required amount of sunscreen needed to achieve the SPF of their product.[48,51–54] Because of this, a method has been developed to determine an approximate volume of sunscreen product needed for adequate protection.[101] This rule states that you should use more than half a teaspoon on each of your head and neck area and arms, and more than a teaspoonful on each of your anterior and posterior torso and your legs. This application size was determined based on the dose used in FDA sunscreen testing (2 mg/m^2). Studies of sunscreen application techniques have demonstrated inadequate application at all body sites.[52–54],[102] The worst protected areas were the ears and top of the feet, and the back was poorly protected if sunscreen was self-applied. Patients should be reminded to apply sunscreen on those often forgotten areas, such as the hands, cheeks, neck, ears, and dorsum of the feet. It is best to reapply the sunscreen every 1 to 2 hours or after sweating, swimming, or toweling off. There is evidence that early reapplication within 20 to 30 minutes be able to partly compensate for initial underapplication.[47,103–105]

CASE 42-1, QUESTION 7: How long might J.J. expect to be protected with the sunscreen properly applied?

If J.J. (skin type II) normally burns after 30 minutes of exposure to the sun, a sunscreen with an SPF of 15 to 30 may provide up to 7.5 hours (0.5 hours × 15 [SPF 15]) of photoprotection from UVB. However, a high SPF product may provide only partial protection against UVA, with little or no protection from infrared radiation.[46] Because of this, sun exposure should be limited to 90 to 120 minutes for each outing after appropriate sunscreen application. Further, environmental factors, such as elevated atmospheric humidity, and inadequate application techniques, may reduce photoprotection by as much as half.

Table 42-4

Relative Ultraviolet Protection Factor (UPF) by Ultraviolet Ray (UVR) Transmission and Absorption

UVR Transmitted (%)	UVR Absorbed (%)	UPF	Protection Category
10	90.0	10	Moderate protection

5	95.0	20	High protection
3.3	96.7	30	Very high protection
2.5	97.5	40	Extremely high protection
<2.0	>98.0	50	Maximal protection

Sunscreen formulations with SPF as high as 50 can be made using combinations of chemical and physical sunscreen agents.[6] Individuals who are extremely sensitive to the sun may benefit from formulations with higher SPF, but the average fair-skinned person gains adequate protection for sunbathing or for average daily exposure from a product with an SPF of 30.[48]

CASE 42-1, QUESTION 8: Would J.J. gain additional benefit from a product with an SPF greater than 50?

Protection from sunburn increases with higher SPF; however, it is important to remind J.J. that this protection does not correlate to the extent of skin damage from UVA rays. One study reported less sunburn in patients who applied SPF 85 compared with those who applied SPF 50 and spent a similar amount of time in direct sunlight.[106] In the FDA amendment that went into effect in 2012, SPF ratings were limited to a maximum of 50+ due to lack of evidence for greater efficacy at higher SPF ratings.[57] J.J. should also be reminded that the SPF is only accurate if he correctly applies the sunscreen in the adequate amount.

PROTECTIVE EYEWEAR

CASE 42-1, QUESTION 9: Recommend appropriate protective eyewear for R.J. and J.J.'s family while they are on vacation.

R.J. and J.J. should wear sunglasses when outdoors to decrease their lifelong exposure to solar radiation and while at the beach to prevent high exposure of UVR and possible photokeratitis or conjunctivitis. Many manufacturers of sunglasses label their products according to three categories: cosmetic, general purpose, and special purpose. Cosmetic sunglasses block at least 70% of UVB, at least 20% of UVA, and less than 60% of visible light and are appropriate for casual wear when high exposure to UVR is unlikely. General-purpose sunglasses block at least 95% of UVB, at least 60% of UVA, and 60% to 92% of visible light and are appropriate for most activities in sunny environments.[107] Special-purpose sunglasses block at least 99% of UVB, at least 60% of UVA, and at least 97% of visible light and are appropriate for very bright environments, such as ski slopes or tropical beaches.[107] Special- or general-purpose sunglasses are appropriate recommendations for R.J., J.J, and their children to wear while on vacation.

Tanning Booths

CASE 42-2

QUESTION 1: B.P., a 32-year-old woman, is preparing for a business trip to Cancun. She is seeking advice about the use of a tanning bed to stimulate melanin for the prevention of sunburn while on her trip. B.P. has skin type III and light brown hair and green eyes. She recently heard, however, that a tan produced by artificial sunlight may not protect against sunburn and may even cause skin cancer. What advice will you offer her?

Most tanning beds, booths, or salons use an artificial light source that emits about 95% UVA with minimal (i.e., 1%–5%) UVB. [108,109] It was originally thought that UVA is much less likely to produce photoaging and photocarcinogenic changes of the skin than UVB; however, UVA has now been found to cause many of the same effects on the skin as UVB, including immunologic, degenerative, and neoplastic changes, as well as damage to DNA and the formation of reactive oxygen species.[110] UVA also contributes to cataract formation and the activation of herpetic lesions.[25] The high doses of UVA received during a tanning session, as well as increasing cumulative UVA doses over time, raise great concern about the long-term effects of UVA. [111] In addition, UVA may augment the photocarcinogenic effect of UVB, [74] and extensive evidence indicates a relationship between indoor tanning and melanoma.[112] Tanning bed use dramatically increased from less than 1% of Americans in 1988 to 27% of Americans in 2007.[113] However, results from the National Health Interview Survey noted a decrease in adults who frequented tanning salons from 5.5% in 2010 to just over 4.2% in 2013. The decrease is hypothesized to be due to increased awareness regarding the harms of tanning. Concern still exists about the number of Americans choosing to tan, especially within the adolescent population.[114] Participants of the 2013 Youth Risk Behavior Survey conducted by the CDC reported that about 13% of high school students, including 20% of high school girls, had used an indoor tanning device one or more times during the last year.[115] This issue is compounded by evidence that suggests that excessive UV exposure, particularly tanning beds, may have a behavioral component similar to other substance-related disorders, which may be related to an endogenous release of opioids secondary to exposure to UV light.[116] As many as 10% to 53% of young adults meet the criteria for having an addictive component to indoor tanning behavior.[117–121] In an attempt to combat the epidemic of use in young people, the FDA reclassified ultraviolet lamps to be class II medical devices in 2014 and include a black box warning indicating that they should not be used by minors 18 years old or younger.[122] Although this act placed more regulation on tanning booths, concern has been raised that regulating tanning equipment as medical devices implies that they offer a therapeutic benefit, and is not commensurate with other products that are known carcinogens with very little to no offered benefit.[123]

With a skin type III, B.P. may be able gradually to achieve a moderate tan with minimal burning, thus providing some protection from UVR because of increased melanization of the skin. This UVA-induced tan, however, may not be as protective as a tan achieved under normal sunlight conditions because UVA does not thicken the stratum corneum.[118] An artificially produced tan plus subsequent sun exposure has not been found to provide any net reduction in long-term damage to the skin when compared with the same amount of tan obtained by sunbathing alone.[118] For these reasons, B.P. should not use the tanning booth to obtain a protective tan, and she should use appropriate photoprotective measures during her trip.

CASE 42-2, QUESTION 2: What precautions would you recommend if she decides to visit a tanning salon?

If B.P. decides to artificially tan despite your recommendation, she should undertake some precautions. The FDA has recommended exposure schedules for first-time users based on skin type, which determines a person's minimal erythemal dose (MED) of UV radiation. The MED is determined by the amount of UV exposure necessary to produce any visible reddening of the skin 24 hours after exposure. This policy suggests that exposure be limited to no more than 0.75 MED 3 times the first week, followed by a gradual increase to maintenance doses of a maximum of 4.0 MED delivered weekly or biweekly.[124] It is important to remember that MED is specific to an individual, and therefore will be different depending on his or her skin type. Correlating the FDA's policy into time limits for an individual is therefore dependent on skin type as well as the amount of UV exposure provided by the tanning apparatus the individual will use. To minimize cataract development, B.P. should always wear protective eye wear that absorbs all UVA, UVB, and visible light up to 500 nm; simply closing her eyes or wearing regular sunglasses provides no protective effect against eye damage.

SUNLESS TANNING PRODUCTS

CASE 42-2, QUESTION 3: B.P. decides to accept your recommendations to avoid tanning beds; however, she would still like to have a tan before going to Cancun. Will the use of sunless tanning agents confer any photoprotection for B.P. against sunburn?

Sunless tanner is a commercial term that denotes a product that provides a tanned appearance without exposure to the sun or other sources of UVR. One commonly used ingredient in these products is dihydroxyacetone (DHA), a color additive that darkens the skin to orange brown by reacting with amino acids in the stratum corneum. The term bronzer is used to describe a variety of products intended to achieve a temporary tanned appearance. For example, among the products marketed as bronzers are tinted moisturizers and brush-on powders. These produce a temporary effect, similar to other types of makeup, and wash off over time. Some products are marketed with other ingredients in addition to DHA to provide a tanned appearance. Generally, neither sunless tanners nor bronzers provide any protective activity to UV exposure by themselves, unless specifically listed with a SPF rating[125] As previously described, the FDA now requires that all suntanning preparations that do not contain sunscreen ingredients are required to carry a warning statement on the label that they do not protect against sunburn.

Tanning pills are promoted for tinting the skin by ingesting massive doses of color additives, usually canthaxanthin. At large doses, canthaxanthin is deposited in various organs, including skin, imparting an orange-bronze color. This color varies from individual to individual. This colorization is not the result of an increase in the skin's supply of melanin. Although canthaxanthin is approved by the FDA for use as a color additive in foods, in which it is used in small amounts, its use in these so-called tanning pills is not approved. Reported adverse events include drug-induced retinopathy, nausea, gastrointestinal cramping, diarrhea, pruritus, and urticaria. None of the above noted unapproved agents should be recommended for use.

Treatment of Sunburn

CASE 42-3

QUESTION 1: G.B., a 31-year-old man with skin type IV, returned a few hours ago from an afternoon of activity in the sun. His shoulders, back, neck, and arms are bright red and are beginning to feel hot, stretched, and painful. G.B. has been otherwise healthy, has no significant medical history, and has no known allergies to medications. What treatment recommendations would you give G.B. for his sunburn?

Sunburn is a self-limiting condition, and treatment is usually symptomatic.[126] Suggested treatments that G.B. can try for his first-degree burn are oral (e.g., ibuprofen, aspirin) or topical (e.g., camphor, menthol) analgesics, topical anti-inflammatory agents (e.g., hydrocortisone cream or aloe vera gel), cooling compresses (tap water, saline, or aluminum acetate solution [Burow solution]) applied to the skin, or cool protectant baths (e.g., colloidal oatmeal). Nonsteroidal anti-inflammatory drugs (NSAIDs), such as aspirin or ibuprofen, may be preferred over acetaminophen because of blockade of the inflammatory prostaglandin-mediated sunburn process; however, although offering symptomatic relief, corticosteroids, NSAIDs, antioxidants, antihistamines, or emollients offer only mild improvement at decreasing the time to recovery.[126]

Topical anesthetics, such as benzocaine or lidocaine, provide only transient analgesia for up to 15 to 45 minutes. These topical agents should not be used in large quantities or applied more than 3 or 4 times a day. In addition, they should not be used on raw, blistered, or abraded skin. Benzocaine has minimal systemic toxicities, but is commonly associated with contact sensitization.[127] In contrast, lidocaine is associated with a low incidence of contact sensitization.[128] Topical corticosteroids have been shown to provide minimal clinical benefit when applied after UV exposure.[129] If G.B. wants to try a topical agent, application or administration is recommended when the pain is particularly bothersome, such as at bedtime. Oral antihistamines may help control pruritus associated with sunburn, as well as aid with sleep, if taken at bedtime; however, no definitive studies have shown benefit in reducing symptoms or benefit of one agent over another.

Treatment beyond self-management is generally unnecessary unless the sunburn is extensive with constitutional symptoms (i.e., fever, chills, nausea, vomiting), involves second- or third-degree burns (particularly if on the eyes or genitalia), or becomes infected. In such cases, referral of the patient to his or her healthcare provider is indicated as a short course (i.e., up to 3 days) of an oral corticosteroid may need to be given (e.g., 1 mg/kg of prednisone or equivalent, given once daily).

Clinical Application of Phototoxicity or Photoallergy

Phototoxic photosensitivity reactions are dose dependent and occur in almost any person who takes or applies an adequate amount of the offending agent. The dose necessary to produce such a reaction varies from person to person and depends on such factors as complexion, hair and eye color, usual ability to tan, and type and amount of UVR exposure. Phototoxic photosensitivity reactions are not immunologically mediated or true allergic reactions; they can occur on first exposure to the agent and generally show no cross-sensitivity to chemically related agents.

A phototoxic reaction usually has a rapid onset, often within several hours after UVR exposure, and presents as an exaggerated or intensified sunburn with erythema, pain, and prickling or burning. Blistering, desquamation, and hyperpigmentation can occur in severe cases.[27,28] Symptoms generally peak 24 to 48 hours after the initial exposure and are usually limited to the areas of UVR-exposed skin. Because phototoxicity reactions do not involve the immune system, prior exposure to the photosensitizer is unnecessary for this reaction to occur. Common drug classes known to be phototoxic include fluoroquinolone, tetracycline, and sulfonamide antibiotics, diuretics, sulfonylureas, nonsteroidal anti-inflammatory agents.

Clinically, photoallergy differs from phototoxicity in that it produces an intensely pruritic, eczematous form of dermatitis.[28] The rash is preceded by pruritus and may subside within an hour. In 5% to 10% of cases, persistent hypersensitivity to light occurs, even after the offending chemical has been eliminated.[27] Photoallergic reactions are not dose-related, and eruptions can also be caused by chemically related agents via cross-sensitivity or cross-allergenicity. As a type of delayed hypersensitivity reaction, time is required to develop an immune response, and the onset of a photoallergic reaction is often delayed for 1 to 3 days. These reactions can present as macular, bullous, or purpuric lesions. Acute urticaria can occur within minutes after UVR exposure. Recovery is slower than from a phototoxic reaction, and it can persist after the offending product has been removed. These reactions may present with erythema and possible edema secondary to the inflammation, but are most commonly found to be eczematous, characterized by erythema; pruritus (possible severe); and papules, vesicles, or both, with weeping, oozing, and crusting. Scaling, lichenification, and pigmentation may occur later.

CASE 42-4

QUESTION 1: D.L., a 16-year-old, blond-haired, blue-eyed teenager with skin type II, presents with a severe sunburn. He states that he started a new summer job 2 days ago with typical sun exposure. He is surprised at the severity of this sunburn, which is worse than normal for the same amount of sun exposure. What further information do you need to know before making treatment recommendations?

Because D.L. is reporting symptoms that differ from previous sun exposures, further questions should be asked regarding the history of the current scenario. Information that may be important in the history of the condition include the temporal relationship between sun exposure and onset of symptoms; the nature and duration of symptoms; recent ingestion or topical application of medications; possible exposure to photosensitizers, chemical irritants, or plants that can cause allergic contact dermatitis (e.g., poison ivy); and the potential for arthropod bites. Information that may be important from the physical examination includes the distribution and morphology of the reaction, as well as areas of the body spared of the reaction.

A drug-induced photosensitivity reaction most commonly appears as a sunburn of greater severity than would normally be expected or as a rash in areas exposed to the sun or tanning apparatus. These reactions can be secondary to oral medications; however, it is important to remember that chemicals with photosensitization potential are found in cosmetics, shampoos, moisturizing lotions, hair dyes or tints, soaps, and other topically applied medications and agents.

Drug-induced photosensitivity reactions can be subdivided into phototoxic and photoallergic reactions. The same medication or agent may produce both phototoxic and photoallergic reactions, and it may at times be difficult to differentiate clinically between the two types of reactions.

CASE 42-4, QUESTION 2: On further questioning, you discover that D.L. first experienced painful erythema of the extensor surface of his hands and forearms, the anterior aspect of his neck, and parts of his face within hours of starting his new job at an outdoor garden and greenhouse. Besides painful erythema, the symptoms also included an immediate prickling and burning sensation. The symptoms continued to worsen until the following morning, about 24 hours after initial exposure to the sun. D.L. does not recall orally ingesting or topically applying any medication or other preparation to his skin, nor does he recall exposure to any chemical irritants, or poison ivy or oak. The morphology of the skin lesions is that of an exaggerated sunburn. The skin lesions are patchy in distribution with greater density on his forearms and hands than on his neck and face. The posterior aspect of his neck and covered areas of his body was spared completely. What are some possible causes of his exaggerated sunburn reaction?

The most likely explanation for D.L.’s exaggerated sunburn reaction is phototoxicity, secondary to contact with psoralen-like chemicals from the plants at his job at the outdoor garden and greenhouse. Photoallergy is another possible cause of D.L.’s symptoms. Although much less common than phototoxicity, photoallergy requires prior or prolonged exposure to the photosensitizing compound.

Presumably, D.L. came into contact with psoralen-containing plants and simultaneous exposure to sunlight. With an unusual distribution of lesions on his hands, forearms, neck, and face and the lack of lesions on areas not contacted by the plants or sunlight, the temporal relationship between the exposure and onset of symptoms places phototoxicity higher in the differential diagnosis. D.L. is unlikely to have a photoallergic reaction because of the lack of a delayed temporal relationship between the onset of symptoms and combined exposure to a psoralen-containing plant and sunlight. Unlike phototoxicity reactions, photoallergic reactions can spread to areas that have not been exposed to sunlight; however, D.L.'s lesions were limited to areas of skin exposed to sunlight.

CASE 42-4, QUESTION 3: What nonprescription remedies might you recommend for D.L. at this time?

General recommendations for the management of phototoxicity and photoallergy reactions are focused on the removal of exposure to the potential photosensitizer and reduced exposure to the sun. Patients should be counseled not to take any medications, orally or topically, without first consulting with their healthcare provider to minimize exposure to other photosensitizers. D.L. should try wearing long-sleeved shirts, pants, and gloves when working to limit exposure to plant photosensitizers. He also may try applying a broad-spectrum sunscreen to protect his skin from UVB and UVA radiation. If these measures do not prevent further photosensitivity reactions, D.L. should consider a different type of employment. His presenting symptoms should be managed in a manner similar to that for an exaggerated sunburn.

PHOTOAGING

Incidence, Prevalence, and Epidemiology

Photoaging, or premature aging of the skin, involves skin changes that differ from those associated with normal chronologic aging.[130,131] Aside from advancing age, risk factors that have been associated with photoaging include fair skin, male gender, high sun exposure, and smoking.[115,132] Because recognizing photoaging and photodamage may prevent the progression or development of skin cancer, it is important that they are recognized as real medical problems, not just cosmetic or aesthetic concerns.

Etiology

Normal aging of the skin involves fine wrinkling of the skin, atrophy of the dermis, and a decrease in the amount of subcutaneous adipose tissue, all of which lead to a state of hypocellularity of the skin.[131] Photoaging involves a chronic inflammatory state induced by long-term exposure to UVA radiation from reactive oxygen species

(ROS), leading to a hypermetabolic state of the skin.[133] Photodamaged skin is characterized histologically by an accumulation of excessive quantities of thickened, degenerated elastic connective tissue fibers (elastosis).[131] Type I collagen predominates in normal skin, but in photodamaged skin, type III collagen increases about fourfold, and the mature matrix of type I collagen slightly decreases.[110] These degenerative changes in connective tissue may be caused by hyperactive fibroblasts or by enzymatic degradation via cellular infiltrates in inflamed skin.[6] The elastic connective tissue then replaces the collagen in the upper parts of the dermis.[133] The ground substance, composed of proteoglycans and glycosaminoglycans, also is increased considerably in photoaged skin.[6] Capillaries in the dermis become dilated and tortuous, resulting in telangiectasias, ecchymosis, and purpura.[131] The epidermis thickens, and epidermal cells become hyperplastic and possibly neoplastic. Large cumulative doses of UVA, UVB, and possibly infrared radiation during the course of a lifetime are strongly implicated as the cause of these changes in photoaged skin.[6]

Photodamaged skin is characterized as being wrinkled, yellowed, and sagging. Mildly affected skin becomes irregularly pigmented, rough, and dry, with mild wrinkles. Moderately affected skin becomes deeply wrinkled, sagging, thickened, and leathery, with vascular lesions.[131] Largely irreversible, severely affected skin can become deeply furrowed and permanently (and irregularly) pigmented, and may manifest premalignant and malignant lesions.[131] Areas of the body most commonly affected are the face, back of the neck, back of the arms and hands, the V-line of the neck of women, and balding areas of the head of men.

Clinical Application of Photoaging

CASE 42-5

QUESTION 1: P.B. is a 38-year-old woman who has enjoyed many outdoor activities over the years. She lives in a moderate climate, with hot, sunny summers and cold winters. She feels that she appears older than other women her age because of wrinkling and color changes of her skin. Her facial color is somewhat yellowish in appearance, and the fine wrinkles at the corners of her eyes and mouth have become more obvious. She has noticed the formation of small brown spots mottling parts of her face, hands, and forearms. P.B. has skin type III, a clear complexion, and skin that is sensitive to soaps, heavy cosmetics, and perfumes. What nonprescription recommendations can you provide P.B. for treatment of her photoaged skin?

Many nonprescription agents known as cosmeceuticals, products marketed as cosmetic products that contain biologically active ingredients, are targeted at reducing visible signs of aged skin. These products include α-hydroxy acids, retinol, ascorbic acid, hyaluronic acid, and lipoic acid. One particular product class widely used is α-hydroxy acids and polyhydroxy acids. In normal concentrations (5%–17%), they are included in many products to lessen the appearance of damage; however, in high concentrations, they are used as facial skin peels because of their keratolytic properties. They have been shown in studies to reduce skin roughness and sallowness; however, minimal impact was seen on wrinkles.[131,134] Topical ascorbic acid and lipoic acid have also been shown to improve skin texture and wrinkles,[135–137] whereas a co-enzyme Q^{10} derivative (idebenone) may reduce skin roughness and fine lines while increasing skin hydration.[138] In patients who choose to use these products, it should be strongly recommended that they wear at least SPF 15 to 30 because they allow for greater absorption of UVR. These agents are not regulated by the FDA and therefore do not have substantial evidence supporting their effectiveness and can be very costly. Emphasis should be placed on protection from the sun, using photoprotective strategies previously discussed.

CASE 42-5, QUESTION 2: Are there any prescription products that you would recommend to P.B. to discuss with her physician?
